THE NON-SUPPURATIVE INFLAMMATIONS OF THE BRAIN, WITH REPORT OF A CASE OF HEMORRHAGIC (MALARIAL?) ENCEPHALITIS.

BY CHARLES L. DANA, M.D., AND M. G. SCHLAPP, M.D.,
NEW YORK.

Forms of Non-Suppurative Brain Inflammation.—The chief inflammatory disease of the brain, and the one with which every one is more or less clinically familiar, is suppurative encephalitis, which causes the various forms of brain abscesses. This is the only type of acute inflammation that, until recent years, has been described definitely in systematic works. Within the last ten years it has, however, been found that there are forms of acute brain inflammation which do not end in suppuration and which are curable. Some of these are distinctly and easily recognized, while our knowledge of others is still imperfect. In sifting out the mass of material which has been contributed to the subject of acute, non-suppurative encephalitis, we find that we can make out the following pretty well recognizable forms:[1]

First: The infectious encephalitis of infants. There is no doubt whatever now of the actual existence of a pathological condition of this kind, although it does not involve the cortex alone, as Strümpell first supposed, but is a more or less diffuse process.

Second: The hemorrhagic polioencephalitis of adults (polioencephalitis superior and inferior).

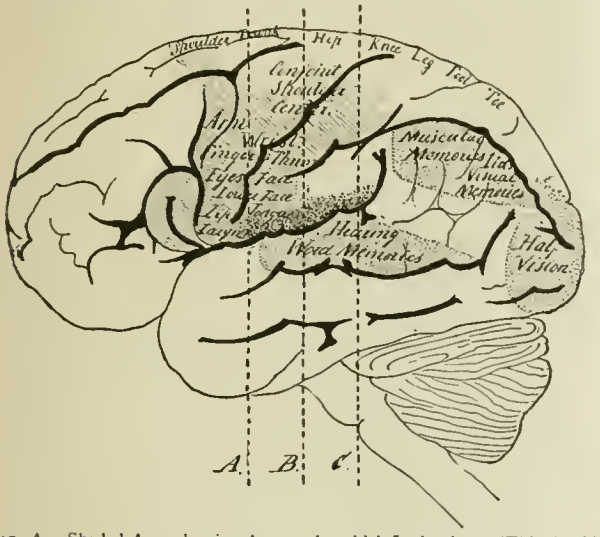

FIG. A.—Shaded Area showing Area under which Lesion lay. (This should represent the right hemisphere.)

This is usually alcoholic in origin and affects the gray matter in the floor of the fourth ventricle, and the aqueduct, causing acute ophthalmoplegia and bulbar palsy.

Third: Hemorrhagic encephalitis of adults, due often to influenza or some other infection, called sometimes an "influenzal encephalitis."

Under this last head we class cases of acute hemorrhagic encephalitis which vary somewhat in cause

FIG. B.—Section through *A*, Showing Location of the Lesion. The darkest spot represents a solid clot of blood.

and symptoms, though always acute, and accompanied with small hemorrhages. It is to this group of "hemorrhagic encephalitis of adults" that the case here reported belongs. The patient was an old man, whereas in most cases hemorrhagic encephalitis of adults affects persons in early or middle life. There was a distinct history of alcoholism, but at the same time no evidence that he belonged to the worst type of such cases; besides this, his blood-vessels were not atheromatous, nor was there a general arterial sclerosis throughout the brain. He had, on the other hand, distinct malarial infection, and it is extremely probable that the influence of a malarial infection, acting upon the blood-vessels weakened by the use of alcohol, led to the condition from which he suffered. Cases of this kind may be classed as those of degenerative, infectious encephalitis, and they lead to clinical types which resemble those of ordinary apoplexy with hemiplegia plus an encephalitic process. Such cases are mentioned by Strümpell; they are, however, certainly rare in the ordinary history of hospital experience. Looking over the records of the autopsies in sixty-seven cases of apoplexy which are in our possession, we find that there were of hemorrhagic apoplexy, 42; embolic apoplexy, 11; thrombotic apoplexy, 11; encephalitic apoplexy, 3. This would give the proportion of encephalitic apoplexies as about four per cent., and that seems to us to represent about the correct number of cases of this kind which we meet with in post-mortem examinations.

The case we have to report seems to belong to the

[1] The history and literature of encephalitis has been recently and fully studied by Oppenheim (Nothnagel's "Special Pathologie," art. "Encephalitis"). A valuable addition to the literature has been made by M. Köppen: "Encephalitis," Arch. f. Psych. Bd. xxx., p. 954.

same class as that described by Köppen.[1] The disease has a tendency to affect the smaller vessels supplying the cortex and the gray matter of the cranial

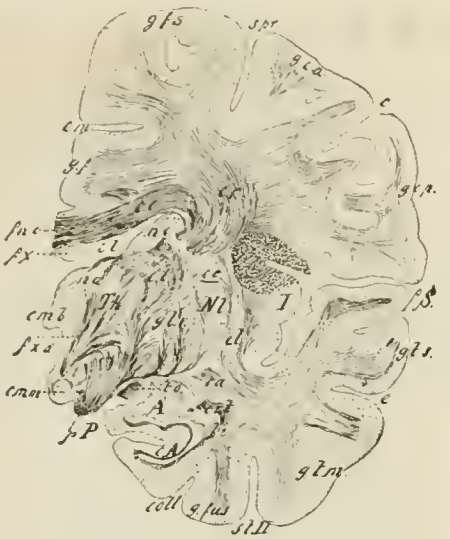

FIG. C.—Section through *B*.

nerve nuclei, though it is not strictly limited to those parts; still it is in contrast to the morbid processes which lead to atheroma of the larger arteries, to miliary aneurisms, embolisms, thrombosis, and massive hemorrhages.

History of Case.—Christian S——, age sixty-seven, German, married; occupation gardener; was brought to Bellevue Hospital on June 4, 1899, in a semi-conscious state. The family history was unimportant, there being no record of apoplexy or paralysis, so far as friends knew. The patient had never used tobacco; he had, however, drunk beer and whiskey all his life, also a great deal of kümmel. The testimony of some of his friends was to the effect that he had been immoderate in the use of alcohol. We could get no specific history. His wife was a healthy woman, but had never had children. He had never been acutely and seriously ill. Fifteen years ago his right leg had been frozen and this had left him with an ulcer which had not healed, but had never been septic. Six years ago he suffered from a sunstroke and ever after was extremely sensitive to

FIG. D.—Section through *C*.

heat. He had become somewhat of an invalid, not doing much work, but going out every day and generally to a saloon to drink beer and play cards. There was some weakness of the extremities during this time, and they were always cold and feeble, but he was not paralyzed. He was a right-handed man.

On June 4, 1899, the patient complained of a headache. He took two cups of strong tea and went to bed at about 8 o'clock P.M. At 10 o'clock he fell out of bed, and was then discovered by his wife to be suffering from left hemiplegia. He was brought in a semi-conscious condition to Bellevue in a carriage. Under medication he rallied and the following day he became conscious. At the time of his admission his temperature was 104.5° F., but it dropped the next day to 99.25° F. and continued so for several days. The pulse on admission was 108, respiration, 34.

A physical examination on June 5th showed him to be a man of good physique and nutrition, but with evidence of his years. He lay in bed conscious and appreciative, but unable to speak a word and quite hemiplegic on the left side. He could not protrude

FIG. 1.—General View of the Seat of Lesion. × 1-inch objective. *A*, *B*, *C*, Hemorrhagic and softened areas.

the tongue, and it lay almost immobile in the mouth. He could, however, draw it back a little and could swallow without much difficulty, showing that there was no paralysis of the throat. His larynx was also normal. He breathed naturally and could make sounds. He was paralyzed almost completely on the left side as regarded the arm and leg and the lower face. He could close the eyes and lift the eyebrows, but the lips were markedly affected. He could not purse them up to whistle. The tongue was somewhat coated. The pupils were even and normal. The heart showed a systolic murmur at the apex. The pulse was full and irregular. The lungs showed some broncho-vesicular breathing posteriorly at the base. The abdomen was somewhat rigid and tympanitic over the iliac fossa. The patella reflexes were normal. Ankle clonus was absent. There was some hyperæsthesia over the left side of the body to touch; sensation to heat and cold was normal. The urine was normal.

The patient continued in about the same condition until the 25th of June, a period of three weeks. Four

[1] *Loc. cit.*

days after his admission he had a chill and temperature of 105.5° F. His blood was examined and was found to contain the plasmodium of malaria. The temperature fell to normal the next day and rose again four days later to 102° F. After that it continued normal until the day of his death. He had thus three attacks of considerable fever and one chill. His paralysis and dysarthria continued, remaining about the same during his illness in the hospital.

A physical examination made by me after he had been in the hospital a week gave the following: He was still partly paralyzed on the left side, the left arm being very weak, the left leg less so. There was no paralysis of the right leg or right arm. The knee jerks of the left side were somewhat exaggerated and there was some rigidity of the arm and leg. The face showed paralysis of the lower portion of the left side. The most notable feature of his condition, as already noted, was the paralysis of the tongue and of the lips. The patient was quite unable to protrude the tongue and could lift it and retract it only slightly. It was practically an immobile organ; he could, however, swallow both liquids and solids without much difficulty. He had, in addition, a paresis of the lips so that he could not extend the lips when told to show the teeth, and could not purse up the lips when told to make the motion of whistling or blowing. The patient was unable to articulate a single word with any distinctness—he made simply inarticulate sounds, and could not even say "yes" or "no"; this, however, was not due to loss of memory of words, but simply to the defect in the peripheral muscles of speech. He could swallow as already stated, and could cough, and there was no evidence of laryngeal palsy. He understood perfectly what was said to him, and he was able to read as shown by various tests. He understood the uses of things and had no evidence in any way of sensory aphasia. His mind was at times confused and he was occasionally somewhat delirious. He had no convulsions or spasmodic movements. The patient died June 25th, three weeks after his admission.

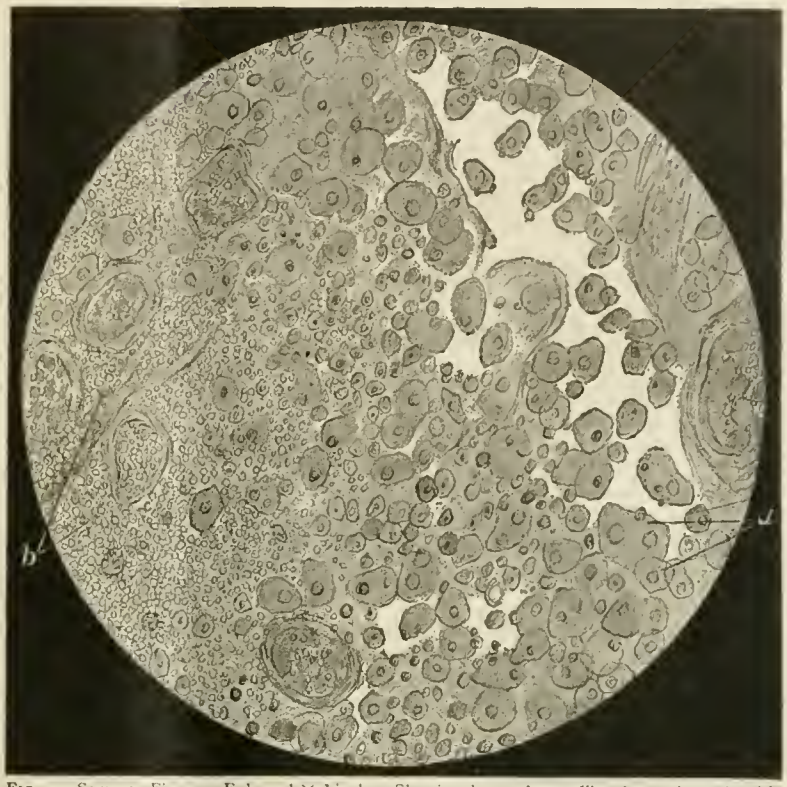

FIG. 3.—Same as Fig. 2. Enlarged × ⅛ inch. Showing hemorrhage, dilated vessels, and epithelioid cells.

FIG. 2.—Softened and Hemorrhagic Area. Indicated at *A* in Fig. 1.

Autopsy: At the autopsy, made by Dr. Dana and the house physician, Dr. Armstrong, on the following day, only the brain and cord could be examined. Upon opening the skull, which presented no anomalies, the dura mater was found non-adherent and normal. Removal of this membrane showed slight œdema and congestion of the pia-arachnoid, but no evidences of hemorrhage or softening in any part. The vessels of the base were not at all atheromatous, and, on following them up in the Sylvian fissure, no evidence of thrombosis could be found. The crura cerebri were cut and the cerebellum was removed with the medulla and pons, and a longitudinal incision dividing the hemispheres was made. Transverse sections were then carried through each hemisphere. In the right hemisphere an area of capillary hemorrhages and softening was found lying in the lower portion of the posterior central convolution and the anterior part of the marginal gyrus. It involved mainly the cortex of the deep part of the upper lip of the fissure of Sylvius and extended for a distance of an inch and a half from the posterior part of the lower end of the posterior central convolution to the posterior end of the fissure of Sylvius (Figs. A, B, C, D). In the centrum ovale to the inter-

nal and upper side of the large lesion were two or three small areas of capillary hemorrhage almost punctate in size. No evidence of hemorrhage or softening was seen in any other part of the brain or in the cere-

Fig. 4.—Showing Epithelioid Cells (Schlapp).

bellum or pons. The spinal cord showed two small foci of similar hemorrhagic degeneration, one in the upper dorsal and one in the lumbar region. The brain and cord were placed in formalin solution until hardened, and were then stained in various ways for the purpose of microscopic study of the diseased part.

General Results of Microscopical Examination.—Sections were made of the brain, medulla, and cord, by Dr. M. G. Schlapp, and stained by Nissl, Weigert, hæmatoxylon, and fuchsin methods.

The brain: The disease was confined to the region described (Fig. 1). There were two specially affected areas, one in the cortex chiefly, the other in the white matter beneath. The former showed enormously distended blood-vessels, small hemorrhages, and round-cell infiltration. The vessel walls were not much thickened. The deeper-lying areas showed small hemorrhages and much softened and destroyed tissue. Here were found lying around the capillaries and small vessels peculiar, large, globular, so-called "epithelioid" cells, which have been described by previous observers and appear to be characteristic of the process. They are perhaps derived from neuroglia cells.

Medulla: There were found here a few very small hemorrhages which must have occurred shortly before death. There were no "epithelioid" cells, which characterize a later stage of the encephalitic or degenerative process.

Spinal cord: The vessels here were enormously distended and thickened. A small spot of recent hemorrhagic softening was found in the second to third dorsal segments and another in the lumbar cord.

The nerves were not examined.

Summary: Relatively large capillary hemorrhagic and inflammatory focus with "epithelioid" proliferation deep in the upper lip of the fissure of Sylvius under the foot of the post-central convolution and involving the anterior part of the supra-marginal convolution. Small and more recent hemorrhagic foci in the medulla and in the spinal cord. Great general congestion and distention of the spinal vessels near the affected areas.

Detail of Microscopical Examination (By Dr. Schlapp).—The location of the different lesions having been described, it remains but to give a brief description of the histological nature of each lesion. That these lesions which are so widely distributed in the nervous system are caused by some toxin circulating in the blood is hardly to be questioned, and in this case the toxin was probably produced by the malaria germs. The blood-vessels, as above stated, were enormously distended throughout the whole nervous system, and in two of the lesions, namely, in the medulla and in the cortex, hemorrhages were found. The lesion in the cortex shows two distinct areas of tissue change viewed with a low-power lens. In the one area which seems to be almost entirely confined to the cortex, we have the enormously distended blood-vessels, the hemorrhages, and the round-cell infiltration. In the other area which surrounds the former but which seems to be confined to the white substance only, one can plainly distinguish a very marked distention of the capillaries. Around the capillaries there is also to be seen the round-cell infiltration, but not to such a degree as in the former picture. The most characteristic appearance of this area is the presence of very large round globular cells. A striking thing about this area containing the epithelioid or globular cells is that it extends to the cortex but not into it. It seems as if the gray matter resisted the penetration of these large proliferating cells.

Viewing the area in the gray matter with a high power, the pia shows to a not very marked degree round-cell infiltration, but is not very much thickened. In the walls of the blood-vessels (which are not much altered) can be seen round cells, and surrounding them these round cells are present in great numbers (Fig. 6); they, however, do not spread very far from the

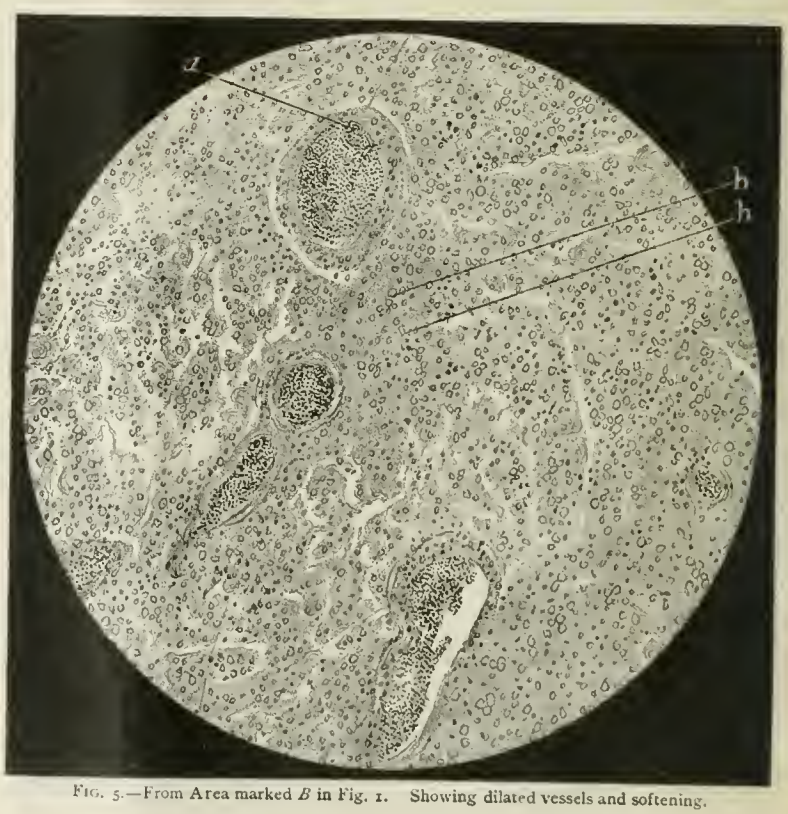

Fig. 5.—From Area marked *B* in Fig. 1. Showing dilated vessels and softening.

vessels. The blood-vessels are enormously distended with blood. The hemorrhages are almost exclusively confined to the gray matter and are of an infiltrating nature (Fig. 2). Brown and yellow pigment particles are

seen throughout the hemorrhagic area. The ganglion cells are destroyed around the hemorrhages; some, however, still showing the nucleus and nucleolus surrounded by a broken and torn mass, the remaining cell

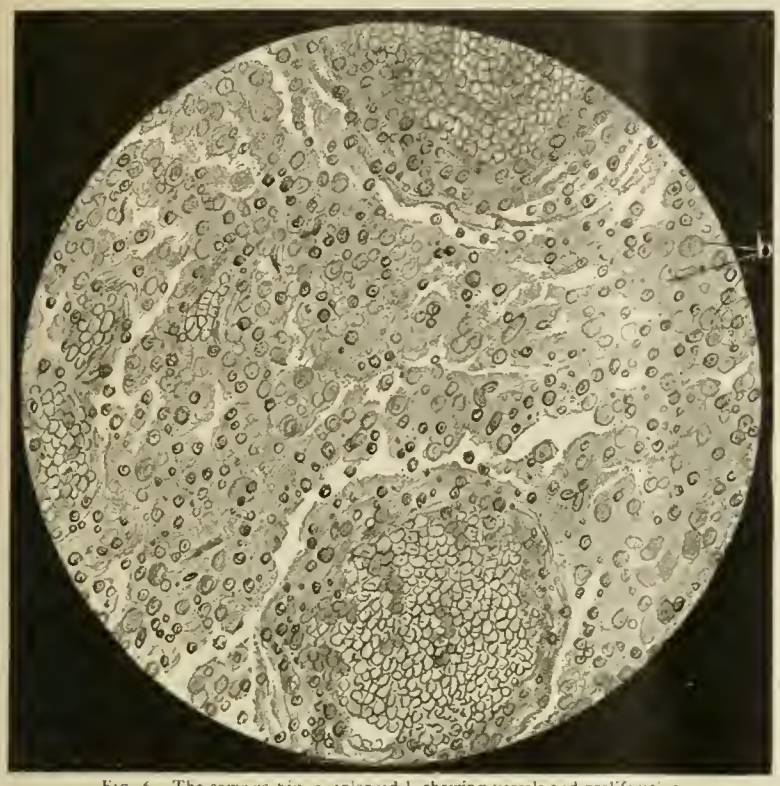

Fig. 6.—The same as Fig. 5, enlarged ½, showing vessels and proliferation.

body. Around the hemorrhages and in the whole infiltrated area the nerve fibres have been destroyed. Here and there a single fibre is seen, thickened, running a very tortuous course, the sheath of Schwann being torn and distorted (Weigert's method). The other area, which, as above stated, is confined to the white matter adjoining the hemorrhagic area in the gray matter, shows very interesting and characteristic features. The capillaries are all enormously distended, the nervous tissue is destroyed, and in its place we find placed side by side large and small cells whose bodies are sharply outlined by what seems to be a membrane. These are the globular or "epithelioid" cells (Fig. 3). The protoplasm of the bodies of these cells shows the network structure. The spaces between the meshes are filled with a homogeneous mass (Delafield hæmatoxylon stain, formol). The nucleus is sharply set off from the protoplasm of the cell. The nuclei of these large proliferating cells do not all present the same appearance in size and structure. One kind is small, round, has more than one nucleolus well defined, usually three or four, and its protoplasm is more intensely stained than the other larger kind (Delafield hæmatoxylon). With the Weigert method this small round nucleus stains intensely black. The other kind of nucleus is large, irregular in shape, usually shows only one well-defined nucleolus, and its protoplasm is not so intensely stained. There are, however, small granules in the protoplasm of the nucleus besides what seems to be the nucleolus, and these granules seem to be connected by a fine fibrillar network. This large nucleus does not stain black with the Weigert method, has rather a reddish tinge, and its nucleolus and granules can be clearly distinguished (Fig. 4). These epithelioid cells are massed in greater numbers around the capillaries, and are smaller here, increasing in size as we recede from them. The nuclei show both direct (amitotic) and indirect (mitotic) cell division. The amitotic cell division is not seen so frequently as the mitotic, and the cell body proper in which the amitotic divisions are taking place is small and irregular in shape, whereas the cell bodies in which the mitotic changes are going on are large, well-developed, and usually regular in shape (Fig. 5).

There were found in the sections no cells which Köppen described as cells having no nucleolus, but instead a mass of chromatic substance lying in the centre of the cell. The greater number of cells contain one nucleus; many contain two (about one-fifth), and here and there one can see a cell having three nuclei. Where this area of epithelioid-cell proliferation meets the relatively healthy tissue, we see these large cells massed in larger numbers; some, however, can be seen entering the normal tissue to some distance like advance guards, but their cell body soon begins to break down. Vacuoles appear in the protoplasm of the cell body, and it finally breaks up in pieces, leaving the nucleus apparently intact and alone, or still surrounded by the remaining pieces of the cell body.

The lesions in the medulla oblongata were confined to several small hemorrhages which must have occurred very shortly before death. There was here and there only a little round-cell infiltration, but no pigmentary deposit. A large number of the cells of the different cranial nerve nuclei throughout the medulla and the ganglion cells in the olivary bodies show pigmentary degeneration. The pigment had, in some cells, entirely replaced the chromatic substance, and in these cells the nucleolus had taken a position at the periphery of the cell-body, in some instances even partly protruding therefrom.

Throughout the whole spinal cord the blood-vessels were distended, and the connective tissue surrounding the blood-vessels was so much increased that in some places even in the nerve roots the nerve tissue seems

Fig. 7.—Showing Spinal Cord, Upper Dorsal Region, Congestion, and Dilated Vessels (Schlapp).

to have suffered from it (Fig. 7). In the region of the second and third dorsal roots there was an area of softening about 1 cm. in length, confined almost entirely to the gray matter. There were deposits of blood pigment in patches around this lesion, and at several places

very small hemorrhagic areas surrounding small blood-vessels (Fig. 8). Scattered throughout the cord in this region, and less so in other regions, there are quite a number of corpora amylacea. A remarkable feature of this lesion consists in the almost entire absence of round-cell infiltration; so that the lesion has not the appearance of an inflammatory one, but looks more like the breaking down of tissue due to occlusion of the blood-vessel or vessels supplying this area.

In the lumbar cord there is an area, however, not so large as the above, and not having progressed so far in its disintegration. The tissue around the blood-vessels is beginning to break down, showing in some instances spaces filled partly with disintegrated tissue. There were no secondary systemic degenerations present in the white matter, but around the large lesion in the dorsal region the sheath of Schwann and myelin substance of the white matter were destroyed in patches here and there.

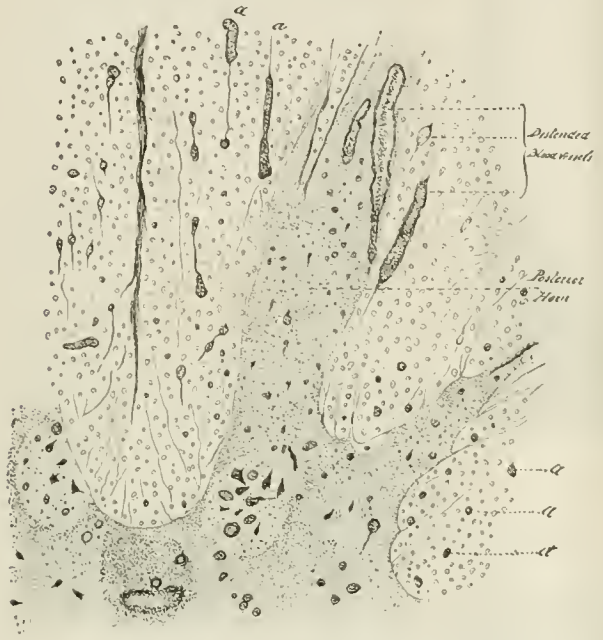

FIG. 8.—Showing Same Area as in Fig. 7. Central canal, Clarke's columns, posterior horn, greatly dilated vessels (Schlapp).

Remarks (By Dr. Dana).—The foregoing case is, as has been shown, undoubtedly an illustration of a form of hemorrhagic encephalitis. It differs somewhat from the ordinary (third) type in that the patient was an old man, whereas in most cases this trouble affects persons in early or middle life. There was a distinct history of alcoholism, but at the same time no evidence that he belonged to the worse type of such cases. Besides this, his blood-vessels were not atheromatous, nor was there a general arterial sclerosis throughout the brain. The undoubted existence of malarial infection is interesting and I believe unique. According to Marchiafava and Bignami,[1] the parasites of malaria do not have a tendency to attack the brain tissue very markedly, while in pernicious malarial fever it is common to find the blood-vessels of the brain filled with the parasites and even many punctate hemorrhages. The authors state that the relative rarity of any nerve changes led them to discontinue any systematic research. The parasites seem to produce special changes in the endothelium of the capillaries, and in very bad conditions small hemorrhages and also chromatolysis and nuclear changes in the nerve cells. Although it seems to be pretty well established that the malarial germs do not have any special tendency to produce reactive changes in the brain tissue, yet when infection occurs in an aged person with the blood-vessels already damaged by a previous sunstroke and the excessive use of alcohol, a destructive inflammation may well be deemed possible. The symptoms are not like those in the more classical cases. In these there is usually a high fever associated with vertigo, vomiting, and delirium, and other symptoms of cerebral irritation followed by symptoms of cerebral depression, such as semi-coma or stupor. There is then often some paralysis such as occurred in this disease, and at times there may be an epileptic convulsion. Perhaps on the whole the chief difference between my own and the ordinary cases is the early occurrence of the apoplexy.

Hemorrhagic encephalitis has to be distinguished from acute meningitis, and from an ordinary cerebral hemorrhage. In encephalitis there are not the stiff neck, the small pupils, or the general rigidity and twitching of meningitis. On the other hand, there do occur occasional convulsions, and sooner or later some form of paralysis. Usually the disease can be distinguished from a hemorrhage or thrombosis by the signs of severe cerebral irritation lasting for from one to four or five days before any paralysis occurs. The fact that the patient has had an attack of grippe, or some severe infection, helps the diagnosis, as does also the presence of some alcoholic history, although alcoholism is not usually present in the grippe cases.

It is possible that examination of the blood and the absence of leucocytosis may assist in excluding the suppurative process. Optic neuritis may occur in this trouble, but certainly very rarely; much less often than in suppurative encephalitis or any suppurative meningitis. There is much practical importance in being able to recognize encephalitis, because the non-suppurative forms are sometimes curable, especially if the paralysis is not extensive. There still remains a good deal to be done, however, in order to enable one to make the diagnosis with certainty.

PRELIMINARY REPORT ON THE PRESENCE AND NATURE OF PARASITIC AMŒBÆ (CANCRIAMŒBA MACROGLOSSA) IN THE EPITHELIAL CARCINOMATA.

BY GUSTAV EISEN, PH.D.,

CURATOR CALIFORNIA ACADEMY OF SCIENCES, BIOLOGICAL DEPARTMENT, SAN FRANCISCO, CAL.

THE following account is intended to be a preliminary report upon parasitic amœbæ found in epithelial carcinomata, which are undoubtedly the cause of the peculiar structure of these tumors and probably of the tumors themselves. The object of this paper is to engage the attention of other workers in this field of research in order that they may with the same methods, or with better ones, corroborate or refute the conclusions at which I have arrived. I have been engaged for several years in the study of the structure of carcinomata and their so-called cell degeneration, but it is only within the last few weeks that I have succeeded in demonstrating satisfactorily, to my own mind, the nature of these cell enclosures or degenerations, so called, and in proving that parasitic amœbæ are certainly the cause of the carcinomatous structure and probably also the cause of the tumor itself. My investigations are not yet so far advanced that a final report is ready, including an account of the reproduction of the parasites and the effect of injections of their cultures into animal tissues. These researches, I hope, will be finished during the present year. In this report I merely wish to set forth the main points in my conclusions, leaving a full review of the subject to some other time.

Cause of Previous Failures.—The failure of my

early investigations as well as those of many other investigators is, I think, entirely due to the methods employed in fixing the tissue. No success was had by the old methods in so differentiating the amœba that it could with certainty be decided if the darker staining centre constituted a nucleus or not. On the contrary it suggested itself to me that this darker centre could best be compared with that part of the cytoplasm known as the sphere, and I based on this supposition a theory which, however, my new researches prove to be erroneous, as the nucleus of the amœba can be most beautifully differentiated by the new method.

Another cause of failure refers to the form of the amœbæ, which by the employment of the old methods could not be ascertained. As will be stated more fully in the next paragraph, the cancriamœbæ are readily contracted, and when in this state cannot be properly studied. All effort must thus be directed toward the instantaneous fixing of the tissue and with it of the parasitic amœbæ, which I take to be the prime cause of epithelial carcinomata (and perhaps also of other forms of carcinomata), and for which I propose the name of Cancriamœba macroglossa, on account of the most characteristic feature—the long snouts—of the animal. There is little doubt that other methods will be found which will differentiate these amœbæ, but the one directly to be described accomplishes this in a manner much superior to any others tried by me.

It is not my intention to claim that the cancriamœbæ here to be described, have not previously been seen. On the contrary, I am satisfied that the organisms found, for instance, by Plimmer are identical, not with the fully developed cancriamœba, but with its spores. The fully developed cancriamœbæ, when badly fixed and contracted, have repeatedly been taken for cell degenerations, cornifications, etc. The methods advocated in this paper are capable of fixing these bodies instantaneously, and in such a manner that no doubt can remain as to their true nature.

Method for Differentiating the Amœba.—This method is based upon the necessity of fixing the amœba while it is yet alive. I found that in all carcinoma tissue which had been allowed to lie for some little time at common room temperature the amœbæ could not be properly recognized as such. Instead of characteristic amœbæ only contracted globules were found, and these were so distorted that no trace remained of their otherwise most characteristic form. Neither was their interior structure (that of the cytoplasm) brought out, nor could their nucleus be differentiated by staining. In such tissue, however, all other cells, when otherwise properly treated, were in perfect preservation; and I concluded that the partial destruction of the amœbæ did not result merely from ordinary decomposition caused by the coagulation of the blood and by other chemical changes. It then suggested itself to me that the contraction of the amœbæ was due to cold. As long as the amœbæ were retained in the warm tissue their characteristic amœboid forms remained distinct, while when exposed to a lower temperature outside the body of the host a contraction would take place which would so distort the form and structure of the amœbæ that they could no more be recognized as such. Acting upon this suggestion I determined to fix the amœbæ, if such they were, before the tissue had time to cool off. Experience further showed that another improvement consisted in warming the fixative to as near blood temperature as possible. This can best be done in a thermostat, but when none is handy it may be accomplished by simply warming the fixative in an inner pocket until the very moment when the tissue is dropped in.

Fixation.—The following fixative has given most excellent results: Bichromate of potassium, 3 parts; glacial acetic acid, 5 parts; water, 100 parts. Use at least twenty times as much fixative as tissue, and change the fixative if there is any sign of cloudiness. The *modus operandi* of fixation is then as follows: Before the carcinoma is operated on, small pieces are cut out, none to exceed one-half cubic inch, smaller slices, say from one-fourth to one-eighth inch in the narrower diameter, being preferable. These pieces while yet warm, and without first having been placed on the table, are dropped in the fixative, which until that moment must have been kept at a temperature as near to that of the blood as possible. It is better to keep up the temperature of the fixative for some little time until the tissue will have become penetrated and fixed. This is, however, not absolutely necessary, as I have had most excellent results by simply keeping the small fixative bottle in my pocket for half an hour or less. After twelve hours' time, or longer, the tissue is taken out and washed in running water until all trace of the color of the fixative is gone. This takes from ten to twelve hours more.

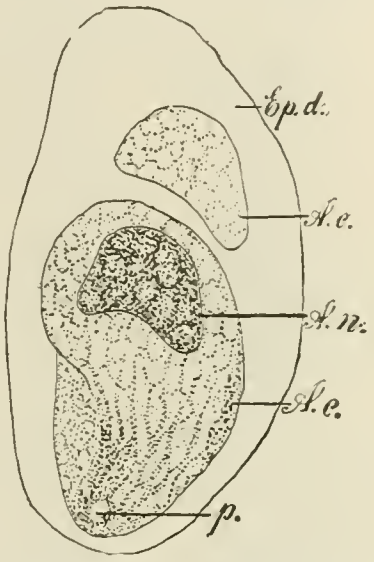

FIG. 1.—A Cancriamœba lying in a Vacuole, the latter being a remnant of a destroyed cell. In the lower apex of the amœba is seen a small vacuole. This part of the body of the cancriamœba is slightly drawn out, forming a tongue-like projection. The darker central part is the nucleus. Above in the same cell is seen a part of another cancriamœba, the main body of which is found in another section.

The after-treatment is the one generally adopted for paraffin work. The tissue is passed through successive alcohols of thirty, fifty, seventy-five, ninety-five, and one hundred per cent. In the latter it must remain over night, a change of alcohol being made once or twice. From the absolute alcohol the tissue is carried through two changes of bergamot oil and two changes of xylol, and again into bergamot oil. This last change is made in order not to cause a too violent evaporation of the xylol when placed in paraffin. The tissue must on no account be placed in the paraffin until it is perfectly cleared. Paraffin melting at 54° C. is preferable, and two changes are sufficient. The preparation of the tissue should not require more than three days, and even this time may be considerably shortened by frequent changes of alcohols and clearing oils. Sections should not be cut thicker than 4 μ, otherwise the amœbæ will not be properly differentiated by the staining-method. The sections are fixed on the slides by the alcohol method.[1] After drying for several hours the paraffin is dissolved by xylol, and the xylol is eliminated by alcohol.

Staining.—From the alcohol baths the slides are immersed in a one-per-cent. solution of Grübler's eosin, soluble in alcohol, and kept there over night or for less time if necessary. The slides are now taken out and placed for some minutes in water until all the alcohol is extracted. The slide must be washed clear of any superfluous stain. The next step is to drop on the slide a one-per-cent. solution of methylene blue "o" in water, to which ten per cent. of alcohol has been added. The action of the latter stain cannot be predetermined, as no two stains are alike. My own solution stains sections 4 μ thick in about five seconds,

[1] See Zeitsch. f. wiss. Mik., Bd. xiv., 1897. p. 195.

but as much as five minutes may be required. After that length of time hold the slide slanting and with a dropper cause a small stream of absolute alcohol to flow over the slide, being careful to place the mouth of the dropper close to the higher edge of the slide. In two or three seconds the tissue is sufficiently washed free of superfluous blue stain, and the slide is then dropped into a jar with bergamot oil, or simply flushed with pure bergamot oil, which must not contain any trace of alcohol. The next step is immersion in xylol and mounting in gum-thus in xylol (or in balsam in xylol if thus cannot be had). If the operation has been successful the tissue will be stained pale red with bluish nuclei, while the amœbæ are intensely red with deep blue nuclei. If the first staining does not differentiate successfully, the tissue may be re-stained one or more times by simply immersing the slides in the eosin bath, thus beginning the process anew. It requires some practice to differentiate the amœbæ properly in the most effective manner, but the above method will not offer any great difficulties even to the beginner. It is, however, entirely useless to endeavor to differentiate the amœbæ in sections thicker than 4 or 5 μ.

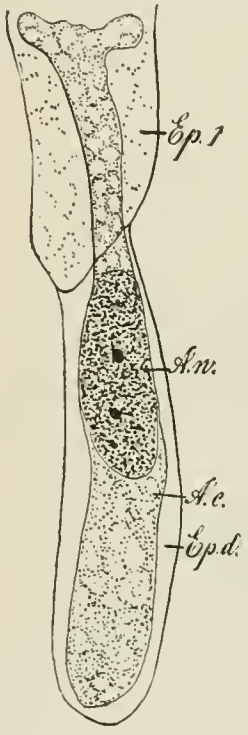

FIG. 2.—A Cancriamœba Fully Extended, entering an epithelial cell, the nucleus of which is not visible in the section. The apex of the cancriamœba is slightly flared and crenulated. The larger part of the body as well as the nucleus of the cancriamœba lies in the vacuole, the latter being the remnant nf an eaten-out epithelial cell. The nucleus contains three small nucleoli.

The nature and structure of the cancriamœbæ will now be considered.

Definition.—Cancriamœba macroglossa, gen. et sp. nov.: Parasitic amœba; diameter of adult specimens from 7–30 μ; body sac-like, pear-shaped, capable of projecting pseudopodia. The cytoplasm is frequently differentiated into a cortical layer and an inner layer. The cytoplasm is of a foamy structure, frequently interspersed with granules of different sizes. The nucleus is large, apparently homogeneous, at times furnished with one to three nucleoli. Propagation by spores is preceded by a fragmentation of the nucleus. Cytophague. Found in all tissues of epithelial carcinomata examined by the author.

In properly prepared sections of epithelial carcinomata the cancriamœbæ are found in enormous numbers all through the tissue, but especially in cell-nests or cell-plugs. The cancriamœbæ are recognized by their shape, which is that of typical amœbæ, by the deep red color of their cell body, and by the deep blue of their nucleus. Many of the larger as well as the smaller specimens lie free in a vacuole. Sometimes there is only one specimen in the vacuole, again there are several or many. The vacuole is caused by the destruction of one or more epithelial cells, which have been eaten out by the cancriamœbæ.

The most characteristic part of the cancriamœba is the projectile snouts. Generally there is but one snout projected, but as many as three have been observed by the author in large specimens. These pseudopodia, which characterize all amœbæ, are also the most characteristic features of the cancriamœbæ. Not only is the pseudopodium used as a locomotive organ, but also as a suctorial one. When the cancriamœba has eaten out an epithelial cell it projects a certain part of the body, in the shape of a foot or tongue, into an adjacent cell, which is in time fully destroyed. Generally only one epithelial cell is attacked at a time, as is seen in Figs. 2–5, but in many instances I observed an amœba which had projected pseudopodia into two or three different cells at one and the same time (Fig. 6). The structure of the pseudopodium is frequently more open than the rest of the body, and at its apex a small pore is sometimes seen. In some cancriamœbæ a distinct vacuole is seen to exist. It can, however, not be demonstrated in all specimens.

A nucleus is always present. It stains intensely blue. It is generally of a polymorphous outline, and in many specimens in a stage of fragmentation. This fragmentation is probably the first stage in the formation of spores. In spermatobium, a parasitic protozoon in the testes of certain oligochæta, the formation of spores has been studied more in detail. Here the nucleus sends out ramifications which gradually separate from each other and then contract, forming small isolated centres of nuclear substances all through the cytoplasm. Each such nuclear centre becomes the central part of a spore. There is every reason to believe that the same process of sporulation takes place in the cancriamœba, and that the fragmentation of its nucleus is actually the beginning of sporulation.

The size of the cancriamœbæ varies considerably. Some few are a little larger than a red blood corpuscle, while others reach a diameter of 30 μ or even over. The form of the body is sometimes strongly elongated, undoubtedly due to the narrow place in which the cancriamœba is confined. At other times the elongated form is the effect of the voluntary effort of the cancriamœba to project itself from one cell to the other. That the cancriamœbæ actually consume the epithelial cells can be proven not only by the pseudopodia of the parasites penetrating into the cells, but more convincingly, perhaps, by observing the actual consumption of the cellular tissue. In many instances we may observe how the granules of the cell tissue are separating from the cell, and we can follow a stream of these granules from the cell that is being eaten into the body of the cancriamœba. These cell granules, after having been taken into the body of the amœba, stain at first just as the granules of the cells, that is, a violet-red, but as the granules are found deeper and deeper in the amœba they are seen to stain deeper red. There is thus every reason to believe that the deep-staining granules of the amœbæ constitute the cell substance of the epithelial cells which are consumed by the amœbæ and gradually have been digested and differentiated in the body of the cancriamœbæ.

Propagation.—The cancriamœbæ propagate both by spores and by amitotic division. In my preparations the amitotic division is the most frequent. The amœba contracts at the centre, each half possessing a part of the original nucleus. The nuclear parts are often of unequal size, as far as can be judged from sections, though it is possible that part of the nucleus may have been cut away. Each half, even before full separation, is often seen to send out pseudopodia into new cells. The propagation by sporulation has been mentioned in the definition, and I have no further details to add to those already given.

The Structure of the Epithelial Carcinomata.—It may be stated at once that the cause of the structure is, in my opinion, due to an effort of the epithelial cells to surround the cancriamœbæ and, by encysting them, to protect the tissue of the human body from being further invaded by the parasites and destroyed by them. The only cells which can do this effectively are the epithelial cells, which on account of their peculiar toughness and size are especially adapted to

perform this work. As soon as a cancriamœba makes its entrance among the cells of the body, the epithelial cells in the vicinity increase with great rapidity and by growing inwardly try to enclose the cancriamœbæ, or, so to say, to fence them in. Hence the large masses of epithelial cells which like large waves approach inwardly from the original epithelial layers of the body. The formation of the cancer cell nest or cancer plug is a secondary consequence of this effort of the epithelial cells. In my preparations this formation of cancer plugs can be readily studied, as they are present in all stages of development. Roughly stated, the formation of the nest is due to several processes about as follows: The centre of the nest always contains one or more cancriamœbæ. This primary cancriamœba increases in size or multiplies by division and thus presses on the epithelial cells and pushes them aside. In this manner the epithelial cells near the cancriamœbæ become flattened out and lunate. Those epithelial cells nearest the cancriamœbæ become the most flattened, those farther away less so. Those epithelial cells situated nearest the cancriamœbæ, and which are not directly eaten by them and thus destroyed at once, evidently succumb either to the possible toxic properties of the cancriamœbœ, or to the pressure exerted on them. It is also probable that these epithelial cells on their own account undergo a certain cornification in order the more effectively to encyst the cancriamœbæ and separate them from the surrounding tissue. This cornification seems in some instances to extend also to the cancriamœbæ themselves, the result perhaps of some infiltration of a cornifying substance or exudation from the epithelial cells themselves. In some instances it is demonstrable that the epithelial cells are eaten up by the cancriamœbæ, the remnants of the former being scattered about. The true structure of a cancer cell nest is thus as follows: In the centre of the nest there is one or many cancriamœbæ feeding on several epithelial cells of general form. Surrounding this group of cancriamœbæ and epithelial cells are seen one or more layers of lunate and strongly flattened epithelial cells. These latter cells often separate from the rest of the epithelial cells, forming a thin-walled capsule more or

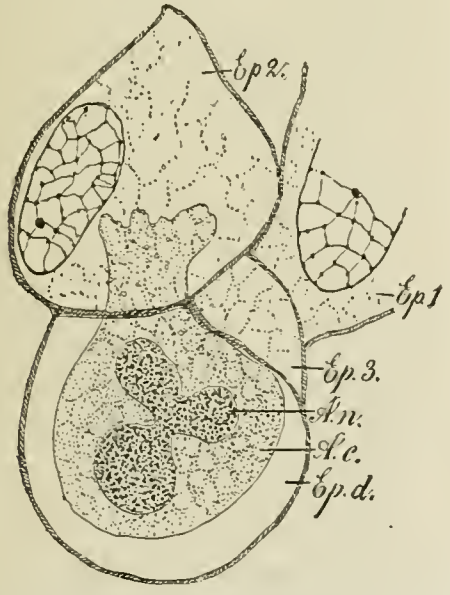

Fig. 3.—A Cancriamœba projecting its tongue like apex from the vacuole in which it is situated, into an epithelial cell (*Ep. 2*). This latter contains a nucleus. The nucleus of the cancriamœba is polymorphous. The vacuole (*Ep. d*) is the remnant of an epithelial cell which has been eaten out by the cancriamœba.

less firmly surrounding the cancriamœbæ. In many instances the cancriamœbæ are seen to be penetrating this epithelial capsule in their effort to get away in order to find new epithelial cells to feed on. There is thus a constant struggle for supremacy going on between the epithelial cells and the cancriamœbæ. Often the amœbæ are seen to have succumbed and are

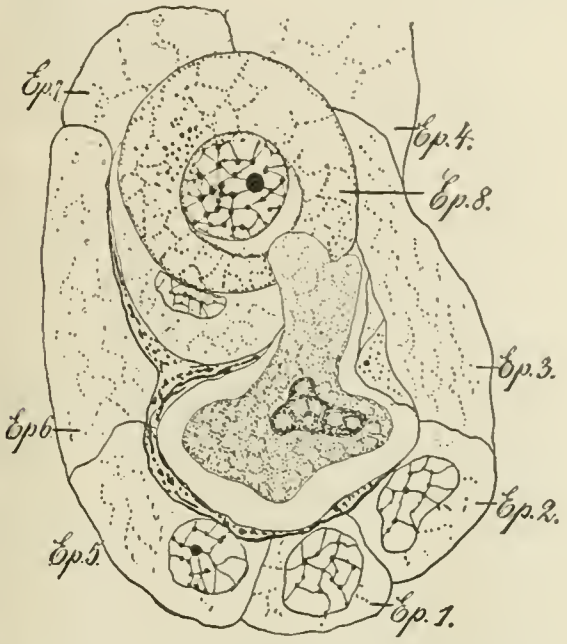

Fig. 4. The Centre of the Cancer Cell Nest. In the central vacuole, which is the remnant of an eaten out epithelial cell, is seen a cancriamœba in the act of penetrating into a healthy epithelial cell furnished with a nucleus (*Ep. 8*). The nucleus of the cancriamœba is slightly polymorphous. In the epithelial cells numbered *1, 2, 5*, parts of nuclei are seen; in the other epithelial cells except *8* the nuclei are seen in succeeding sections. Between the cancriamœba and epithelial cells *6, 5, 1*, and *2* are seen dark and irregular bands, probably remnants of epithelial cells destroyed by the amœba.

found firmly enclosed by the cell nests and apparently in a dying condition, or fully dead and solidified. But in the majority of cell nests the epithelial cells seem to be the losing ones, the cancriamœbæ escaping to other parts. The vacuole surrounding the parasites is the place formerly occupied by epithelial cells eaten by the cancriamœbæ. In innumerable places the cancriamœbæ have been fixed in the very act of penetrating into the epithelial cells, and it is this view of them which is to me the most convincing one as regards the true nature of the parasites. Their identity with amœbæ is unmistakable. Not only is the form of the body and the formation of the spores characteristic of amœbæ, but the presence of pseudopodia excludes the possibility that we here have to deal with blastomycetes or other fungi.

The leucocytes of the blood seem not to be attracted by the cancriamœbæ, at least I have nowhere seen any indication of a struggle between them and the parasites. In some instances cancriamœbæ may be seen which have actually swallowed erythrocytes and parts of erythrocytes, but nowhere have I seen remnants of leucocytes in the cancriamœbæ, or *vice versa*. This is probably due to the manner of feeding of the parasites. They appear to consume only small particles of cytoplasm at one time, absorbing them by the aid of the apex of their snout. The latter is nearly always flared at the point intruded into the cell, the very apex forming an absorption surface, strongly indented or crenated in order to present a large surface to the cytoplasm of the cell. A most interesting fact noticed is that the cancriamœbæ are frequently found with one part of the body in one cell while the other part is situated in another cell. Or different parts of the same individual cancriamœba may be projected out into several different cells while the main part of the body remains in its vacuole. This demonstrates to my mind conclusively that we have before us an extra-cellular organism and not any degenerations or chemical transformations. Such degenerations could not possibly assume the function of actual protozoa, that is,

they could not project parts of their own mass into adjacent cells. It is also of importance to note that in all such individuals occupied in phagocytosis of epithelial cells, the nucleus is generally polymorphous, a form especially effective in promoting and facilitating an exchange of metabolic products between nucleus and cytoplasm. In cancriamœbæ which are not thus engaged in phagocytosis (Fig. 1) the nucleus is generally more compact, barely showing an indented outline.

In tissues treated by the methods suggested in this paper the cancriamœbæ appear without any perceptible distortion and contraction, and any one acquainted with these animalcules cannot fail to recognize at once their true nature. They do not appear as mere contracted lumps of protoplasm, but may be seen as if in the very act of crawling about with extended pseudopodia. It is fully evident that the vacuole which nearly always surrounds the cancriamœba is entirely due to the destruction of one or more epithelial cells. The remnants of the cytoplasm of these cells are often found in the vacuole, but what is yet more convincing of the nature of the vacuole is that the shrunken and partly destroyed nuclei of these cells are now and then seen in the vacuole. Their presence could not be explained except by the supposition that they are the actual remains of cells which have been destroyed by a cancriamœba.

As regards the number of cancriamœbæ in the tissue nothing definite can be stated. They occur there in enormous numbers all through the tissue, either singly or in nests. In the centre of some nests there will be seen only a few cancriamœbæ, but in other and larger nests they may be counted by the hundreds. The centrally situated cancriamœbæ are generally thicker and less elongated, while those situated nearer the margin of the nest are thin and long, often bending in a semicircle around those situated nearer the centre of the nest. This form is due, I think, to the inability of the cancriamœbæ to develop in any other direction, the epithelial cells on the outside of the nest only slowly yielding to the constantly increasing cancriamœbæ. When such nests finally cause the surrounding epithelial tissue to yield, the cancriamœbæ together with the remnants of epithelial cells, more or less fully consumed, are set free, and it may then be seen that in such places the cancriamœbæ are more or less rapidly regaining their natural form.

A distinction can always, with some little practice, be made between cancriamœbæ and leucocytes. The body of the former stains much more deeply with the eosin than that of the leucocytes; besides, the leucocytes are nearly always smaller, the cancriamœbæ being generally many times larger than the leucocytes. The nuclei of the cancriamœbæ are also quite distinct from those of the leucocytes, being more solid and homogeneous than those of the latter. Taking it all in all, by a little practice the cancriamœbæ can readily be distinguished from all other cells, provided the tissue has been successfully fixed and stained.

Solidity of the Cancer-Plugs.—The increased hardness of tissue containing cancer-plugs is well known to every student of these structures. This hardening of the plug is caused by two things. As the epithelial cells are being eaten out the cell walls remain and form more solid masses nearest the amœbæ, and as the cell walls are more solid than the cytoplasm of the cell it explains the increased toughness of the plugs. But besides this concentration of cell walls there appears also to take place a chitinization of the cells nearest to the amœbæ, and this chitinization seems also to extend to some of the amœbæ, which in this way are effectually destroyed.

Are the Cancriamœbæ Accidental Inhabitants of Carcinomata, or Are They the Cause of the Structures Characterizing Carcinomata?—This question has partially been treated in the preceding paragraphs. Without producing carcinomata by the injection of cultures of cancriamœbæ this question cannot be fully answered. At present we must confine the question to whether the cancriamœbæ are the cause of the peculiar structures known as cell nests or cell plugs, or whether they simply inhabit them. This point, I think, can be most readily answered. In all the carcinomata examined by me two facts are evident—first, no cell nests are found which do not possess one or more cancriamœbæ in their core; second, while many cancriamœbæ are found free among the epithelial cells, many are also seen to be surrounded by a few cells of a primitive cell nest. By studying a large number of such cell nests a perfect series may be had from the most primitive one, consisting of only a few epithelial cells enclosing a centrally located cancriamœba, to fully developed cell nests consisting of numerous, concentrically arranged cells enclosing numerous cancriamœbæ. There can be thus no reasonable doubt that the cancriamœbæ actually cause the formation of the cell nests. As these cell nests are the characteristic structure of the epithelial carcinomata we may, I think, expect that it will be proven that the cancriamœbæ are also the cause of the carcinoma itself.

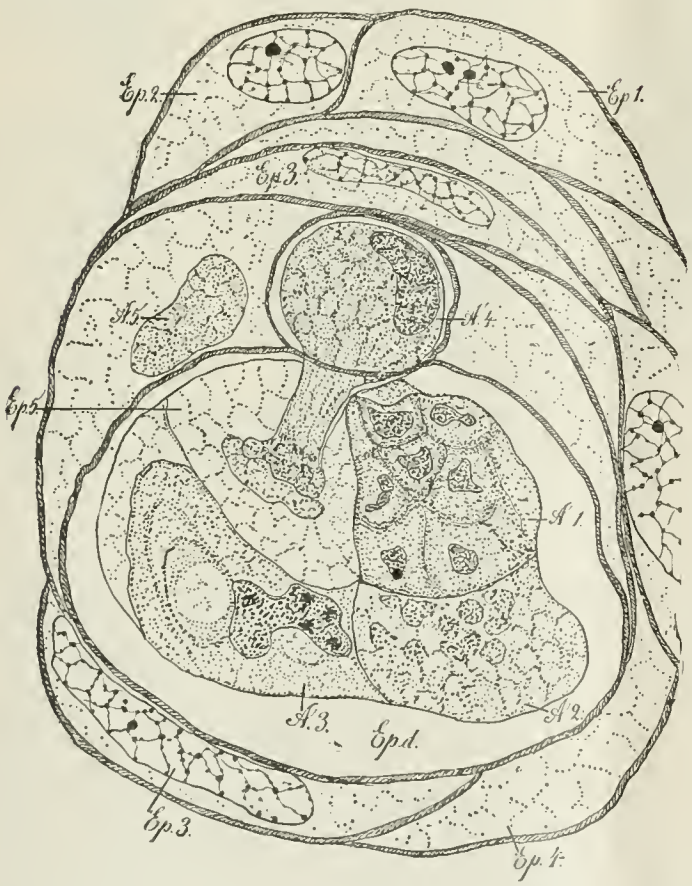

FIG. 5.—The Centre of the Cancer Cell Nest. *A 4* is a cancriamœba in the act of penetrating from the vacuole to another epithelial cell (*Ep. 5*) in which is seen the partly destroyed nucleus. Adjoining this cancriamœba are three others in various stages of sporulation. In *A 2* the nucleus had undergone a fragmentation but the spores are not yet sufficiently formed to be recognized as such. In *A 1*, however, the new spores are quite distinct, having formed around a fragment of the nucleus. *A 3* is a cancriamœba with polymorphous nucleus and a vacuole. *A 5* is part of a cancriamœba, the other part of which is seen in the following section. This group of amœba-infested epithelial cells is surrounded by many other epithelial cells of concave form, and which have not yet been eaten out by the cancriamœba. The large central vacuole (*Ep. d*) is the result of the destruction of several epithelial cells, which have been eaten by the amœbæ.

I may here add that so little time has passed since I found the method of differentiating the cancriamœbæ that I have had no time to examine many carcinomata pertaining to the type in which cell nests are not found, and I am consequently not able to state to what extent cancriamœbæ are found in such cancers. But I have during the last few days examined two cancers of this type prepared by the new method, and both these cancers were found swarming with the same cancriamœbæ as in the other class. The want of cell nests is probably due to some peculiar condition of the epithelial cells, but investigations have not yet proceeded far enough to solve the question fully.

Summary.—1. A parasitic amœba (Cancriamœba macroglossa) is found in all epithelial carcinomata. This amœba may be readily fixed while in action if the tissue is fixed while yet warm, the lowering of the temperature below that of the blood causing the amœbæ to contract.

2. The cancriamœbæ are the cause of the characteristic structure of epithelial carcinomata in which are found cell nests or cell plugs. In each such nest we can always distinguish two distinct parts—an inner core or amœba nest consisting mainly of one or many cancriamœbæ mixed with some leucocytes and loose epithelial cells, and an outer zone consisting of epithelial cells, the inner one of which are flattened, concave, and in section lunate, while the outer ones are normal.

3. The peculiar structure of these cancer plugs is caused by the effort of the epithelial cells of the infected locality of the human body to fence in the amœbæ and prevent them from spreading through the tissue. This effort is also more or less successfully accomplished by an enormous increase in epithelial cells and by a chitinization of the cells nearest the cancriamœbæ. The concentric structure of the cancer plug is the result of the pressure on the epithelial cells caused by the cancriamœbæ situated in the centre of the cancer plug through continuous increase in number and size.

4. A constant struggle is going on between the cancriamœbæ and the epithelial cells. The latter are trying to fence in the amœbæ and to kill them by encysting or by chitinization, while the amœbæ on their side feed on the epithelial cells by projecting pseudopodia into the cells and sucking out their cytoplasm. The cancriamœbæ are not caryophagues.

5. The propagation of the cancriamœbæ is by spores and by amitotic division. Mitotic division has not been observed. There are numerous cells in mitotic division all through the tissue, but these cells seem to be exclusively epithelial cells.

6. The cancriamœbæ are nearly always found surrounded by a small vacuole. This vacuole is the result of the destruction of one or more epithelial cells by the parasites. The vacuole becomes gradually larger as more and more cells are destroyed, until finally when the epithelial cell fence gives way and breaks up a large pus cavity is formed, containing cancriamœbæ, fragments of epithelial cells, and leucocytes.

7. The cancriamœbæ are distinguished from all leucocytes by their larger size. While the leucocytes seldom reach 10 to 12 μ in diameter, the cancriamœbæ frequently exceed 25 to 30 μ in length. Many of the cancriamœbæ possess a vacuole, an organ never found in the leucocyte.

8. The acute sensitiveness to cold suggests the treatment of carcinomata by freezing.

Explanation of the Figures.—All the figures have been studied with a Zeiss apochromatic 2 mm., ap. 1.40; oc. 12. The outlines were drawn with a camera and then redrawn on a larger scale. The details were filled in diagrammatically, imitating as near as possible the natural structure. The cancriamœbæ appear in the preparations deep red with blue, generally homogeneous nuclei, sometimes containing one to three nucleoli. The cell walls have in some of the diagrams been shaded, in others only indicated by black lines.

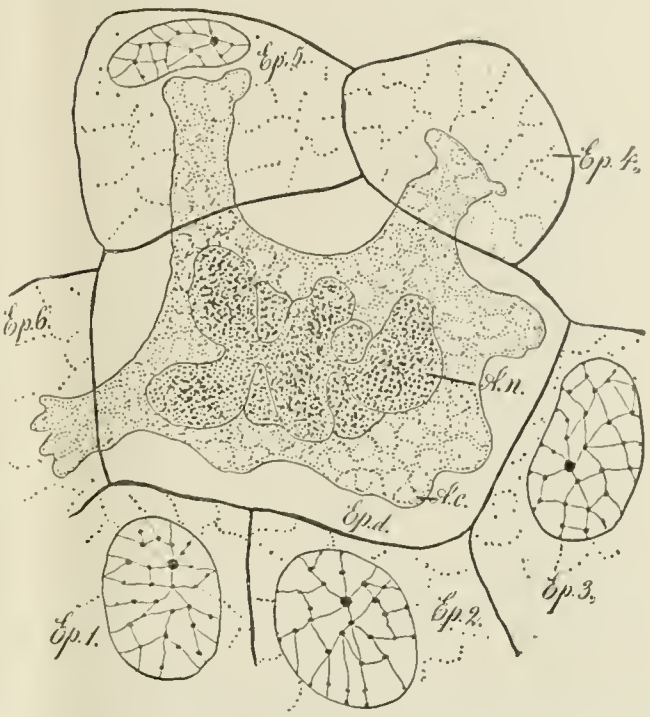

FIG. 6.—A Large Polymorphous Cancriamœba, lying in a vacuole and extending prolongations into three different epithelial cells at the same time. In one of these (*Ep. 5*) a nucleus is seen. In the others the nuclei have been cut away. The nucleus of the cancriamœba is strongly polymorphous.

The following letters refer to all the figures: *Ep.* (numbered), epithelial cells, not yet destroyed by the cancriamœba; *Ep.d.*, epithelial cells already destroyed, and now forming a mere vacuole in which are situated one or more cancriamœbæ; *A.c.*, one or more cancriamœbæ macroglossa; *A.n.*, nucleus of the cancriamœba; *p*, vacuole of the cancriamœba.

819 MARKET STREET.

THREE CASES OF VASCULAR TUMOR OF THE ORBIT: TWO CURED BY OPERATION, ONE APPARENTLY CURED SPONTANEOUSLY.[1]

BY CHARLES STEDMAN BULL, A.M., M.D.,

NEW YORK.

CASE I.—Large venous nævus of orbit and lid. Miss E. W——, aged forty-one years, first seen January 14, 1898. The patient has been a teacher for many years, and her eyes have been under a more or less constant strain. Refraction is hypermetropic and astigmatic. Vision is normal with correcting glasses. The media are clear and fundus is normal, though slightly hyperæmic. The field of vision is normal; tension normal. About two years before I saw her, she first noticed a slight protrusion of the right upper lid, coming on in the morning after she had risen, and increasing somewhat toward evening. It remained about the same size for eighteen months, but since then it has steadily increased in size, and during the last two months has grown somewhat rapidly. At first it always disappeared during the night or after she lay down, but of

[1] Read before the American Ophthalmological Society in Washington, D. C., May 1, 1900.

late it has been constantly present. When I first saw her, there was partial ptosis, the lid covering about three-fifths of the cornea, but it could be completely raised by the united action of the levator palpebræ and occipito-frontalis muscles. The tumor presented just above the middle of the right upper lid, as a distinct congeries of vessels showing blue through the skin. This mass of blood-vessels involved the upper portion of the lid and could be followed inward and backward along the nasal wall of the orbit. There was neither pulsation nor bruit, and there had been no pain at any time. Any forced muscular exertion, lifting, coughing, or forced expiration caused a distinct increase in the size of the tumor, and stooping or bending toward the ground produced a rapid increase in size so far as entirely to close the eye, and this condition did not subside for about five minutes after resumption of the erect position. When she lay on the back for fifteen minutes there was a perceptible diminution in the size of the tumor. A careful examination of the nasal meatus and naso-pharynx revealed an hypertrophy of the turbinated bones and cystic disease of the right middle turbinated bone, with a subacute laryngitis. On the inner aspect of the left thigh just above the internal condyle of the femur, there was a large purple nævus, about two and a half inches in diameter and of an irregular circular form, with some elevation above the surrounding skin, and a similar nævus somewhat smaller on the inner aspect of the left tibia just below the condyle. These nævi had existed for many years. Pressure upon the tumor with the finger caused its complete disappearance within the orbit, but it reappeared as soon as the pressure was discontinued. There was no sign of a similar growth in the other orbit. There was no cardiac complication of any kind.

After a careful study of the case on several visits, it was decided to try what could be effected by electrolysis, though I had never employed this method of treatment in so old a patient. The first application, lasting five minutes, produced no apparent effect. Between February 17 and November 19, 1898, electrolysis was applied sixteen times, at intervals of varying length. Then the patient was obliged to absent herself from observation for a period of three months, when the electrolytic treatment was resumed and continued at intervals of four days for a month. This method of treatment produced some consolidation in the tumor, but no diminution in its size. It was then decided to attempt its excision.

On March 14th the patient was prepared for the operation under the strictest antiseptic precautions. She took the anæsthetic, ether, extremely well, and was profoundly anæsthetized in about six minutes. I was about to make the preliminary incision, when the tumor suddenly increased rapidly in size and extended in all directions, upward upon the forehead, inward over the bridge of the nose, outward upon the temple, and downward upon the side of the nose, and soon reached the size of an orange. The skin covering this area was of a dark purple color and was very tense. The anæsthetic was at once discontinued, and all operative procedures were temporarily postponed. The enormous swelling began slowly to subside as soon as the patient recovered consciousness, but did not entirely disappear for two days. She remained in the hospital till the end of March, and as I went off duty on April 1st I did not resume charge of the case until the following October.

When I saw the patient again on October 1st, the condition was about the same as it had been in the preceding March, and it was decided to attempt the removal of the tumor by excision.

On October 11, 1899, the operation was performed under cocaine anæsthesia hypodermically. Two injections were made, each of ♏ xx. of a five-per-cent. solution of cocaine into the mass, one on the temporal side and one on the nasal side. An incision was made, an inch and a half long, just beneath the superior orbital margin, through the skin and tarso-orbital fascia, care being taken to avoid incising the tendon of the levator muscle. The index finger was then introduced through the wound for exploratory purposes. No distinct tumor was found, but a mass of enlarged vessels was discovered filling the whole nasal side of the orbital cellular tissue, extending back nearly to the apex of the orbit and upward along the roof of the orbit. The bleeding was somewhat profuse. No opening into the ethmoid cells or frontal sinus was found. The mass of connective tissue and enlarged vessels was separated as rapidly as possible from the eyeball and periosteum, and then grasped by a pair of stout forceps with very broad blades. The mass then was put on the stretch, being drawn forward and upward, and a stout catgut ligature was then passed around it, pushed back as far toward the apex of the orbit as possible, tied tightly, and the ends were then cut off. Much of the bleeding then ceased, and an examination showed that the pulley of the superior oblique and the belly of the muscle were uninjured. After all active bleeding had ceased, the cavity in the orbit was carefully irrigated and packed with iodoform gauze. The patient did very well. There were no secondary hemorrhage and very little oozing. The dressing was left undisturbed for three days, and was then removed, the cavity was again washed out, and the gauze packing re-applied. Fresh dressings were applied every two days for two weeks, at the end of which period the cavity had filled up from the bottom. The wound in the skin was then closed by six sutures. One month after the operation, the improvement was very marked, but there were still some bulging and protrusion at the inner end of the upper lid, and the enlarged vessels could be distinctly seen through the lid.

On December 7, 1899, a second operation was done, under the hypodermic injection of cocaine, for the removal of the palpebral portion of the growth. An incision was made through the skin of the lid, about an inch long and extending toward the top of the bridge of the nose. The skin was dissected up in all directions, and the mass of enlarged vessels was then grasped with the same broad forceps and rapidly separated from the tarsus as far as the inner angle of the orbit and lacrymal bone, where there seemed to be quite a firm connection with the periosteum. The mass was then tied off in a similar way with a catgut ligature. There was but little hemorrhage, but the wound was packed with gauze as at the first operation. This was removed on the fourth day; the wound was carefully cleansed, and closed by three sutures. The result was very successful, and on April 18th the scars were scarcely visible; there was no protrusion or discoloration, and only a very slight condition of ptosis. The two masses of tissue and enlarged vessels were examined by Dr. Dixon, the pathologist of the eye infirmary, who reports as follows: "The specimens submitted by you are composed of fat, loose connective tissue, a large number of blood-vessels, and a few cavernous spaces, with considerable extravasation of free blood into the tissue. Diagnosis, caverno-angioma."

Case II.—Pulsating tumor of the orbit. J. B——, aged twenty-three years, was first seen September 2, 1889. Two years before I saw him, he had received a violent blow on the right side of the head by a large timber falling from a height. He was unconscious for two days, and then slowly regained his senses. There was a large, irregular scalp-wound running from the middle of the sagittal suture downward and forward

across the parietal and squamous bones as far as the middle of the zygoma. He said that he understood that no fracture of the skull had been found. He was confined to his bed for two months, with more or less constant headache and mental torpor. When he first attempted to walk, he staggered and complained of dizziness, but does not remember that he ever had diplopia. The tendency to vertigo gradually diminished, though the attacks still come on at irregular intervals. He never fully regained his physical strength or mental vigor. For some weeks after the accident the eyelids were swollen and bruised as if from subcutaneous extravasation of blood, and there was an extensive hemorrhage beneath the conjunctiva, downward and on the nasal side. Somewhat more than a year after the accident, the upper lid began to swell and the eye to protrude, and these symptoms have steadily increased up to date. The headaches have also become more continuous, and are always worse when he bends forward or stoops.

When I saw the patient, the right eye protruded forward and downward, but was freely movable in all directions except upward, in which direction its motility was limited. The upper lid was much enlarged and drooped over the eye, was of a dark red, almost dusky hue, and pulsated strongly. The whole eyeball also pulsated visibly, and a very distinct thrill was communicated to the fingers when placed upon the lid. On auscultation, a harsh blowing sound was heard over the closed lids, on the right side of the forehead, and on the right temporal region, like the exhaust of steam pipes heard at a distance. The media of the eye were clear; the retinal veins were engorged, tortuous, and pulsating. Vision was $\frac{20}{30}$ in the right eye and $\frac{20}{20}$ in the left eye. A rough broken ridge of bone was discovered on the floor of the orbit, running backward from the inferior orbital margin near the inner canthus, and another sharp edge of bone at the infero-temporal angle of the orbit was found which ran backward and inward toward the median line. Pressure on the common carotid artery on the right side, just below the region of its bifurcation, caused an immediate and marked diminution in the pulsation and bruit, and in the prominence of the eyeball, but it could not be continued for more than four minutes, because of an apparent marked interference with the breathing produced by the pressure.

There seemed to be no doubt that the accident two years before had caused a fracture at the base of the skull, involving the floor of the orbit and probably the optic foramen. The main point to determine, if possible, was whether the pulsating tumor evidently existing in the orbit behind the eyeball was a pure arterial aneurism of the ophthalmic artery and possibly of the ciliary arteries, or whether the fracture extended farther back and involved the internal carotid artery and the cavernous sinus. The history of severe traumatism and the gradual development of all the orbital symptoms would seem to favor the idea of aneurism of the ophthalmic artery. But this lesion is rare and has been found in very few cases. The more frequent lesion of laceration of the carotid artery within the cavernous sinus is always due to fracture at the base of the skull, and the orbital symptoms generally develop somewhat rapidly within a few weeks after the injury. In my patient the orbital symptoms did not develop until a year after the receipt of the injury. It may be here remarked that the literature of this subject is quite extensive, but our exact knowledge of such cases is relatively very small.

It was thought best to try what could be effected by compression of the common carotid in the neck, first by the fingers, and afterward by a pad devised for the purpose; but all these efforts were abandoned at the end of the first week on account of their interference with respiration. It was then decided to ligate the right common carotid, which was done under the strictest aseptic precautions. The incision was made in the usual place and followed the inner border of the sterno-mastoid muscle, extending from just below the cricoid cartilage nearly to the sterno-clavicular articulation. Careful dissection exposed the artery without any difficulty; the sheath was opened and the aneurism needle was gently passed between the sheath and the vessel and around the artery till the end appeared in the incision. The ligature was then passed through the eye, and the needle was withdrawn, the ligature coming with it. The latter was then slowly and firmly tied. No vessels of any size were wounded in the operation. All pulsation and bruit ceased immediately in the tumor. The wound was then closed, covered with iodoform, and a small pad and bandage were applied. The wound healed rapidly, but the patient was kept in bed for two weeks. On the fourth day there was a return of the bruit and thrill to a slight extent, but no positive pulsation, and these symptoms continued with varying intensity for nearly six weeks. Even after the patient was discharged, he was kept under observation for more than a year, and there was a slight thrill perceptible to the fingers, though auscultation revealed no bruit. Somewhat more than a year after the operation, the patient contracted pneumonia, which rapidly involved the entire right lung, and he died on the eighth day. I endeavored to procure an autopsy but was unsuccessful, and I am still ignorant of the exact pathological condition of things in the orbit. The protrusion of the eyeball gradually subsided, and its motility was restored to the normal condition. The vision was immediately impaired by the operation and sank to $\frac{1}{200}$, but in about three weeks it began to improve and finally rose to $\frac{20}{100}$. The fundus immediately after the operation was very pale but gradually regained an approximately normal appearance, though the retinal arteries never attained their normal calibre.

Case III.—Pulsating tumor of the orbit. Mrs. T. W——, aged thirty-nine years, was first seen January 9, 1899. This patient had had more or less occipital headache for nearly six months, and had pain in the right orbit for nearly four months. Three months ago the right eye began to protrude. Four weeks ago the right upper lid began to droop, and this ptosis increased. On examination I found complete ptosis, and complete paralysis of all the branches of the right third nerve, including the branches to the sphincter iridis and to the ciliary muscle. The exophthalmos was forward and outward and could not be reduced by pressure. The eye could be moved toward the external canthus. The media were clear and the ophthalmoscopic examination was negative: R.E., V = $\frac{20}{100}$, and with + D 3 = $\frac{20}{30}$; L.E., V = $\frac{20}{20}$. Nothing could be discovered in the orbit by palpation, and there was no bruit or pulsation, nor any thrill.

A careful examination of the nose, naso-pharynx, and ears revealed nothing but a chronic catarrhal condition of the mucous membrane and a moderate amount of hypertrophy of the turbinated bones on the right side. There was no evidence of trouble in the maxillary antrum. The patient was seven and a half months pregnant with her eighth child. The urine was examined and was of normal specific gravity, acid, clear, light straw color, and contained about one per cent. of albumin, but no sugar and no casts. The heart sounds were normal, and there was no hypertrophy. There was no history of any injury to the head nor of any traumatism. The patient was put on small doses of potassium iodide and carefully watched. There was a slight improvement in the ptosis, but none in the motility of the eyeball or in the exophthalmos.

On Jaunary 29th the patient complained of a sharp pain in and around the orbit, and of a constant rushing noise in the head on the right side, which had come on suddenly two days before, and sounded like the falling of water from a height. There was a well-marked thrill on palpation over the closed lids, a slight visible pulsation to the eyeball, and a well-marked bruit on auscultation over the eyeball, forehead, and temple. Deep pressure over the carotid artery in the neck produced no appreciable effect upon either the pulsation or the bruit.

On February 6th the patient complained of an obstruction in the right nostril, but an examination showed nothing more than a swollen mucous membrane.

Owing to her advanced pregnancy it was thought wiser to wait until she had recovered from her confinement before attempting any operative treatment. On March 21st she was delivered of a rather small but healthy male infant, the labor being brief and without instrumental assistance. There was almost immediate relief from the pain in the head and orbit, which had become continuous until her confinement was over. Ten days after delivery a purulent discharge appeared from the left ear, not accompanied or preceded by any pain.

On April 12th the thrill under the finger was particularly marked at the inner canthus and over the internal angular artery. There was a slight visible pulsation of the eyeball, and a strong blowing sound was heard over the eyeball, forehead, and temple, and indistinctly at the vertex and over the malar bone. She complained of a constant dull ache in the eye, but the severe pain in the head and orbit had disappeared after the birth of the child and had not returned. The discharge from the left ear had ceased, and the perforation in the drumhead was closing, but she complained of constant tinnitus. No effect on either pulsation or bruit was produced by compression of the carotid in the neck. The pulse was 132 and regular. There was no enlargement of the thyroid.

On April 23d there was a marked improvement in the ptosis and in the motility of the eye and in the exophthalmos. The bruit was less audible and the pulsation less noticeable. The patient did not complain of the noise in her head, and said that it sounded very much farther away.

On June 1st all bruit and pulsation had ceased, the ptosis was nearly gone, the eye was freely movable in all directions, and the protrusion much diminished. The tinnitus in the left ear was perceived only when she was tired or excited, and the hearing had improved. This patient has not been seen since, but the case looks like a spontaneous recovery.

FISTULA IN ANO: ITS RELATION TO PHTHISIS.[1]

By SAMUEL G. GANT, M.D.,

PROFESSOR OF RECTAL AND ANAL SURGERY, POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL, NEW YORK CITY

Fistula in ano is a very common affection; in fact it occurs with greater frequency than any other disease found about the anal region. It is not uncommon in the well-to-do, but is met with more frequently in people living in crowded communities. Out of the 16,060 cases of rectal diseases treated in St. Mark's Hospital, London, from 1872 to 1891, as compiled by Cooper and Edwards, 8,497, or a little more than fifty per cent., were treated for fistula in ano in some form. Of these 5,829 were men, and 2,668 women. This is about the usual percentage as regards the sex. I have not found in my work, however, that fistula occurs as frequently as all other rectal diseases combined. In dispensary work I find that about one person in three has fistula. The proportion of fistulæ to other diseases is not so great in the upper circles of society because their occupations are not so arduous, they are not exposed to inclement weather, and do not live in densely populated districts where tuberculosis is common. The rectal surgeon is frequently called upon to treat patients suffering from fistula in ano, whose condition is aggravated by coughing, the result of lung involvement, and I dare say the general practitioner in turn sees many phthisical patients who under the very best treatment fail to improve because of the exhausting discharge from an anal fistula.

Fistula and phthisis occur in the same individual with a regularity that cannot be explained by mere coincidence. At the present time I have under treatment three men and one woman suffering from fistula who have tuberculosis of the lungs. In order to show the proportion of fistula to phthisis Allingham reports 1,632 cases of fistula operated upon, and of this number no less than 234 had phthisis. From the analysis of the statistics of others, together with my own, I have arrived at the conclusion that from four to six per cent. of all phthisical patients suffer from fistula, while a much larger percentage of those afflicted with fistula have phthisis. It is extremely difficult to arrive at the correct ratio of the one disease to the other; for instance, a patient going to his family physician for a lung complaint does not deem it necessary to tell him that he has a fistula. On the other hand, when a patient goes to the surgeon to have a fistula cured, the latter will at once suspect lung involvement because of the patient's cough and general debilitated condition. Medical and surgical writers not long since believed there was some anatomical or pathological connection between anal fistula and the lungs, and as a result advised against operation for the cure of fistula. They maintained that in case the operation was successful and the sinus healed, there would be no outlet for the discharge. As a result the existing lung trouble would be made worse, and the patient would die. In case phthisis did not exist before the cure, it would develop as a result of retained poison finding its way to the lungs.

The trouble with these gentlemen was, they had the cart before the horse. I do not doubt that phthisis is frequently a cause of fistula, but I am extremely sceptical if fistula is ever an etiological factor in phthisis. I do not wish it understood that I believe all fistulæ are the result of tuberculous lung disease, for in fact not more than one in six or eight are caused by it, the remainder being the result of abscess induced by exposure, trauma, foreign bodies, and pyogenic bacteria. I will not attempt to discuss simple fistula as seen in robust persons, but will confine my remarks to a study of fistulæ in tuberculous subjects. Of these we have two kinds (1) true tuberculous fistulæ, the result of localized deposits; (2) fistulæ induced or made difficult to cure because of the cough and lowered vitality, the result of phthisis.

1. True tuberculous fistulæ are nearly always secondary to intestinal ulceration, which in turn is secondary to tuberculous disease in some other organ, especially the lung. Tubercle bacilli may gain admittance to the intestine in our food, but most observers hold to the opinion that intestinal tuberculosis is the result of the swallowing of sputum containing tubercle bacilli. It appears that their vitality is not materially interfered with by the gastric or intestinal contents. This, however, may be partly explained by the impaired digestion coincident with general tuberculosis.

2. Non-tuberculous fistulæ are frequent in phthisical

[1] Read before the Medical Association of the Greater City of New York, June 11, 1900.

patients. They are troublesome to treat, for several reasons: (*a*) persons having general tuberculosis are particularly prone to suppuration from slight causes; (*b*) because of the absence of fat in the ischio-rectal fossa, large blood-vessels are left unsupported and readily become dilated and congested; (*c*) lastly the constant coughing of phthisical patients is most noticeable at the anus, and frequently results in bruising of the parts, causing abscess and fistula.

Differential Diagnosis.—The symptoms and general characteristics of tuberculous fistulæ are so different from those of the ordinary kind, that it is not a difficult matter, if one is careful, to differentiate between them, as will be noticed from the following comparison:

FISTULA.

Non-tuberculous.	*Tuberculous.*
1. Internal and external openings small and round, the edges red, and situated in the centre of an elevation.	External and internal openings large and triangular, edges of a bluish tint and drooping into the opening.
2. Buttocks rounded and supported by fat.	Skin undermined.
3 Hair about the buttocks normal.	Abundant, long, and silky.
4. Nails normal.	Nails clubbed.
5. Face and ears and nose normal.	Face pinched, nostrils wide open, ears large and sticking out prominently from the head.
6. Voice natural.	Voice husky.
7. Complexion ruddy.	Complexion sallow.
8. Rarely loss of flesh.	Loss of flesh considerable and rapid.
9. Discharge slight and yellow.	Profuse, whitish in color, and watery.
10. Introduction of probe causes considerable pain.	Introduction of probe causes slight pain.
11. Appetite normal.	Appetite poor.
12. Digestion good.	Digestion bad.
13. Sleep natural.	Interrupted and occasionally disturbed by night sweats.
14. Discharge contains principally colon bacilli.	Discharge contains tubercle bacilli.
15. Not accompanied by hæmoptysis or cough.	Frequently complicated by hemorrhage of the lungs and annoying cough.
16. Tight sphincter.	Patulous anus.

During examination of a fistula the first and most important thing is to determine if it is simple or tuberculous in character. This point can be settled by the finding of the tubercle bacilli by the aid of the microscope; their presence in the discharge makes it almost certain that there is localized tuberculosis, yet they are occasionally found when sputum from a tuberculous lung has been swallowed. On the other hand, there may be tuberculous disease and the bacilli not be present. When the tuberculous process is progressive and the stools are watery, the bacilli become mixed with the fæces and difficult to locate. To overcome this difficulty, Rosenblatt administers sufficient laudanum to produce hardened stools, and then examines the muco-purulent discharge coming away upon the surface of the fecal mass. In this way he has little difficulty in demonstrating their presence. I have frequently examined the pus from tuberculous fistulæ without finding the bacilli of Koch. In such cases I then curette the abscess and fistula wall and examine the débris. By this procedure I have never failed to find them or little caseous bodies, which positively prove the tuberculous nature of the disease. When neither is found, we can safely conclude that the fistula belongs to the non-tuberculous type.

Treatment.—Modern surgeons pretty generally agree that the ordinary fistula, as found in vigorous persons, should be operated upon and the wound allowed to heal by granulation. There is, however, some difference of opinion among both physicians and surgeons, even in this enlightened age, regarding the operative procedure for the relief of tuberculous as well as the simple form of fistula complicated by phthisis. It has been my custom to operate on all fistulæ, irrespective of the kind, and the results obtained have been equally satisfactory to the patients and myself. It is the condition of the patient that should determine if an operation is necessary, and not the fact that he is suffering from this or that form of fistula. I believe we are justified then in operating upon all patients suffering from tuberculous fistulæ in its strictest sense, and those who have simple fistula with or without lung complications, provided their general condition will permit it. I would not operate upon a fistula in a person who would die of phthisis in the course of two or three months, neither would I operate for fistula in a person similarly afflicted with Bright's disease. Each case should be a law unto itself, and the treatment given should be the best for the case in hand, be it palliative or operative.

Palliative Treatment.—In non-operable cases we should use our best efforts to make our patients comfortable and improve their general condition.

1. This is accomplished by keeping the fistulous openings free, thus encouraging drainage.

2. Assist healing and relieve pain by copious injections, or the application of caustics, stimulating, antiseptic, and soothing remedies.

3. Entice the appetite and supply palatable foods, known to have nourishing qualities.

4. Stop all medication which disturbs the stomach and irritates the intestine.

5. Administer oils, creosote, and other medicines which tend to improve the patient's general condition.

6. Do not keep these patients in bed in a dark room; on the contrary allow them the fresh air, sunshine, and the sea breeze or proper altitude when near the ocean or mountains.

7. Make things pleasant and cheerful for them, for their lot in life is not a happy one, and their mental state is occasionally pitiable in the extreme. To relieve pain and induce sleep medication should be given by mouth or hypodermic injection. By following these suggestions, we can at least make all of our patients comfortable and cure not a few through palliative measures.

Anæsthetics.—Having decided that an operation is necessary, a suitable anæsthetic must be selected. Local anæsthesia should be practised when feasible. Of these local anæsthetics I have derived the most benefit from cocaine and orthoform. The former is injected freely along the line of tissues to be severed, the latter is dusted over abscess cavities and fistulous sinuses to be curetted. These agents lessen but do not entirely obliterate pain during operation. In the selection of a general anæsthetic for this class of cases chloroform should have preference over ether or the A. C. E. mixture: (1) It renders the patient unconscious in a shorter time; (2) patients recover from it more quickly; (3) they vomit less after it, thus obviating strain at the anus and a possible hemorrhage; (4) it does not provoke inflammation of the lungs or kidneys. From personal experience I have been forced to the conclusion that many of the deaths from lung complications following shortly after fistula operation are the result of an inflammation induced by the administration of ether, and are not due to the cutting and cure of the fistula.

Operative Treatment.—We should endeavor to build our patients up to a high standard before operating. The morning preceding operation a mild laxative may be administered; strong purgatives never, because they frequently start up a diarrhœa difficult to control. In other respects these patients are prepared as for any other operation. I will not mention the various operations devised for the cure of fistula in ano, and will describe those only which are best suited for the class

of cases under discussion. They are three in number: (1) ligation; (2) division; (3) excision.

Ligation: The ligature operation was first described by Celsus. It consists in passing a silk, wire, or elastic ligature through the sinus and out at the anus, where the ends are securely tied. It gradually cuts its way out, usually requiring from a week to ten days. The following are some of the advantages claimed for it: (1) It does away with the knife; (2) it can be performed without an anæsthetic; (3) it is comparatively painless; (4) there is no bleeding; (5) the patient can walk about, having the benefit of the fresh air and sunshine. The ligature method is not suited to the treatment of fistulæ in general, as (1) it takes a longer time to effect a cure; (2) it does not sever branch sinuses. This operation, however, is especially adapted to the treatment of tuberculous fistula as well as the simple variety complicated by phthisis, since it does not deprive such patients of the air, sunshine, and exercise, and causes little pain.

Division: This is the usual operation for fistula, and is performed in the following manner: A director of suitable size is introduced through the sinus until its distal end can be reached by the finger in the rectum, when it is withdrawn and rests across the anus. The bridge of tissue resting thereon is then divided. Next the back part of the sinus is incised, and the whole tract curetted, irrigated, and packed with gauze. If it is a true tuberculous fistula, every vestige of the involved area should be destroyed with the Paquelin cautery before the dressings are applied. The sphincter muscles should be handled very carefully, for it is after these operations that incontinence is likely to follow.

Excision: The excision of fistulous tracts is not a popular operation, because the results from it are not so good as from the operation just described. It consists in dissecting out the sinus and the immediate closure of the wound, with the object of obtaining primary union. Occasionally it is successful; more often it is a failure because of infection through the rectal end of the wound. Some surgeons maintain that this operation is especially suitable in the treatment of tuberculous fistula because a large suppurating wound is avoided. I agree with these gentlemen that it is better suited for this than other forms of fistula, yet I would not give it preference over the ligature or division operations.

I will conclude my paper with the following observations:

1. Tuberculous fistula of the anus is usually secondary to tuberculous disease of the lungs.

2. Pulmonary phthisis is rarely, if ever, secondary to fistula in ano, either before or after operation.

3. Tuberculosis of the anal region should be dealt with radically, as is recommended when it attacks other parts.

4. When the patient's general condition will permit we should operate on all fistulæ irrespective of the kind.

5. We should not refuse to operate on persons suffering from a mild form of phthisis, nor on those who give a family history of tuberculosis. Certainly, if we arrest one destructive process, nature is all the more capable of dealing with the other.

6. I believe that those patients operated upon for tuberculous fistula and those that are non-tuberculous complicated by phthisis, who rapidly decline and die, do so as the result of an inflammation of the lungs induced by the anæsthetic, especially ether. Such accidents have not followed any of the operations which I have made under local anæsthesia.

7. Lastly, I believe we are justified in discarding the erroneous teachings of writers who believe that the cure of a fistula will result in a development of phthisis.

58 West Fifty-sixth Street.

A Case of Pseudokeloid after Syphilis.—Yordan distinguishes true keloids from pseudokeloids. The latter appear only after traumatisms and in some cases after syphilitic ulcers. He reports a case of his own observation, in which, after rupia syphilitica, many pseudokeloids appeared all over the body; the pseudokeloid character of the scars was proven by microscopical examination. Anti-syphilitic treatment in those cases is of no value.—*Meditsinskoe Obozrenie*, April, 1900.

Median Osteotomy of the Hyoid Bone.—Maurice Vallas holds that this operation is simple, easy, and in itself benign, and that it enables the surgeon to reach the pharynx and to examine its inferior portion and the vestibule of the larynx better than does suprahyoid pharyngotomy. The indications for the operation are foreign bodies, benign removable tumors, cancers limited to the epiglottis, and above all severe syphilitic constrictions. The procedure greatly facilitates the removal of intra-muscular tumors at the base of the tongue, and permits total amputation of the tongue in cases of cancer of the posterior portion of that organ. Neither deformity nor functional disorder follows osteotomy of the hyoid bone.—*Revue de Chirurgie*, May 10, 1900.

Pseudo-Appendicitis.—R. Condamin and J. Voron report several cases which seem to indicate that hysteria or neuropathies are capable of creating morbid conditions which closely simulate the local symptoms of appendicitis, without causing a rise of temperature or modifying the general condition. In addition syphilis causes pseudo-appendicitis. Syphilitics are apt to suffer from enteralgia, and should this pain be situated in the vicinity of the cæcum and the appendix, and should there be at the same time any fever such as is so liable to be present in cases of untreated secondary syphilis, the symptoms will certainly resemble a somewhat severe case of appendicitis.—*Archives Provinciales de Chirurgie*, May 1, 1900.

Cerebral Tuberculosis in Children.—Leone Maestro reports two fatal cases. The first was that of a child aged four years, with tuberculosis of the corpora quadrigemina. There were gradual emaciation and enfeeblement; pulse somewhat intermittent. Convulsions occurred; there were convergent strabismus of both eyes, paralysis of the motor muscles of the iris, dulness of hearing, uncertainty of gait, and finally ataxia. Death occurred six months after the appearance of the first symptom. In the second case, that of a child three years old, the chief symptom was pain in the frontal region. At the autopsy, in addition to basilar meningitis, there was found one tubercle situated in the right side of the cerebellum. The frontal lobes were normal, and the pain was probably a symptom of compression. —*La Riforma Medica*, May 15 and 16, 1900.

Voluntary Luxations.—Francesco Parona reports a case of voluntary or habitual luxation of the left shoulder. The patient was a girl aged seventeen years, and the dislocation had first appeared when she was eight years old, a few months after she had had a fall. She could put her shoulder out of joint at any time; there was no asymmetry, swelling, or other deformity, and when the bone was in place the left arm could be used as freely in every direction as the right. The author decided to operate, and, having opened the capsule, found that the head of the humerus was perfectly formed, and the serous and cartilaginous tissues were normal. Having made folds in the capsule, he stitched them down, and the possibility of dislocating the joint was prevented. The patient made a good recovery, and the cure had been perfectly maintained two years later.—*Il Policlinico*, May 15, 1900.

MEDICAL RECORD:

THE DIFFERENTIATION OF DEFORMING ARTHRITIS, GOUT, AND RHEUMATISM.

THE time is ripe for a more refined differentiation of the various diseases in which joints may be involved. It is well known that arthritis may result from several causes—traumatic, toxic, infective, primarily or secondarily, and in association with disease of the nervous system—but among the different forms there stands out prominently one that can be distinctly recognized as a definite clinical entity, in which successive joints become the seat of pain, redness, and impaired mobility, with acid sweats and elevation of temperature, often complicated by inflammation of the endocardium and the serous membranes, and yielding therapeutically, with almost specific promptness, to salicylic acid and its salts. This disease we know as acute rheumatism or rheumatic fever. It may pursue a subacute course, or leave behind chronic changes in the joints. This disorder is almost certainly dependent upon bacterial activity, although opinions are not agreed as to the identity of the causative micro-organism.

In addition, as has been suggested, inflammation of one or more joints may occur as a complication of various infectious diseases, as for instance scarlet fever, influenza, smallpox, syphilis, gonorrhœa, pyæmia; but this condition cannot properly be considered rheumatism.

The pains in muscles and fibrous tissues, and even in joints, that often appear after exposure to cold and like influences, may not be rheumatic at all, but may be, rather, manifestations of metabolic disturbance, and due to alterations in the fluids of the body, in consequence of which certain substances are thrown out of solution, and act as irritants, generally or locally.

Finally, so-called chronic rheumatism may be considered as representing a number of forms of chronic arthritis of varied origin.

Except in their common involvement of joints, there is no relation between rheumatism, gout, and deforming arthritis, and error in diagnosis should not occur, if careful investigation is made in the individual case. Some of the points of differentiation are discussed by Luff[1] in a recent communication. This observer contends that rheumatism may occur as an abarticular as well as an articular disorder, manifesting itself in the form of chorea or erythema, or endocarditis or pericarditis. Rheumatism, unlike deforming arthritis, is not attended with hyperplasia of articular cartilage, osteophytic outgrowths, and grating of the ends of the bones. The rheumatic joints often undergo fusiform enlargement from thickening of the articular capsule.

In the differentiation of deforming arthritis and gout, it should be borne in mind that the former occurs most commonly in females, the latter in males; the former among the poor and ill-nourished, and especially under conditions of depressed health, prolonged anxiety and exposure to damp, and sudden alterations of temperature, the latter among the well-to-do and the well nourished. The one disorder is improved by good dieting, and the other by a spare and plain diet. Deforming arthritis sets in insidiously; gout suddenly. The latter most commonly appears first in one of the feet, especially a joint of the great toe; the former, although ultimately affecting frequently many joints of both hands, almost always begins in one joint, most commonly one of the joints of the thumb, and spreads rapidly to other joints. The joint affection of deforming arthritis is at first unattended with obvious swelling and marked redness, while that of gout is attended with swelling and redness, and a glossy appearance of the overlying skin. Deforming arthritis is attended with little pain at first. There is some aching, but the onset is insidious. Gout begins with severe pain, the patient as a rule being awakened in the early morning with excruciating pain in the great toe. The temporo-maxillary articulation is commonly affected in cases of deforming arthritis, but not in cases of gout. The lesions of deforming arthritis are remarkably symmetrical in the hands, while this feature is wanting in cases of gout. Finally, sodium biurate can be found in the joints in cases of gout, but not in cases of deforming arthritis.

A disorder has been described as chronic villous arthritis,[1] which is characterized by chronic inflammatory enlargement and hyperplasia of the villi of the synovial membrane, while the cartilage and the bone of the articular extremities remain uninvolved. The affection may be seated in one or several joints, and is attended with pain, enlargement, and deformity and with impaired mobility and functional inefficiency. It differs from deforming arthritis essentially in the involvement of the synovial membrane rather than the articular cartilage and the adjacent bone.

ANOTHER INDICTMENT AGAINST THE MOSQUITO.

THE more we learn of the mosquito in her rôle of transmitter of disease the more clearly does she show forth as one of man's most deadly enemies. She of the Anopheles tribe is proven to be the active agent in the transmission of malaria from man to man; it is claimed by Findlay and others, with apparent reason, that the mosquito is instrumental in the spread

[1] Schüller: Berliner klinische Wochenschrift, 1900, Nos. 5, 6, 7.

of yellow fever, though whether this is the only means (if a means at all) of transporting the disease, and what kind of mosquito carries the germ, we do not yet know; and it has long been an accepted belief that the other species of mosquito (Culex) is the intermediate host of filaria nocturna. In the latter case, however, it has been supposed that the parasite was liberated in water on the death of the mosquito and that man became infected by drinking such water. The mosquito was therefore simply a passive agent, culpable in having bitten a filaria-infected man but guiltless of the infection of healthy individuals. It seems now, however, that this is not the case, or at least not always the case, and that the insect may be the active agent in inoculating man with this dangerous parasite.

In some recent work on a series of filarial mosquitos at the London School of Tropical Medicine, George C. Low has found the mature worm in the proboscis of the mosquito evidently ready to enter the blood of the next victim of the insect's bite (*British Medical Journal*, June 16, 1900). It is now known that the mosquito does not necessarily die immediately upon depositing her eggs in the water, but can, if fed, go on living and laying eggs for many weeks; and Low has found that the filariæ do not remain passive in the thoracic muscles of the mosquito after issuing from the stomach, but leave that tissue and travel toward the head of the insect and pass into the loose cellular tissue in the neighborhood of the salivary glands. They are, of course, too large to pass through the salivary duct, as is the case with the malarial parasite, but they bore their way through the base of the labium and push forward along the proboscis. "It is difficult," Low says, "to avoid the deduction that the parasites so situated are there normally, awaiting an opportunity to enter the human tissues when the mosquito next feeds on man."

If this observation is shown to be correct, it will only add emphasis to the warning against exposure to mosquito bites in the tropics and sub-tropics, and will stimulate to greater activity those who are searching for a certain means of protecting man against these literally pestiferous insects and for some efficient culicicide.

TYPHOID FEVER IN PARIS.

Our Paris correspondent, in the Medical Record of June 23d, calls timely attention to the importance of the sanitary condition of Paris during the Exhibition, when the city is overcrowded with people from all parts of the world, and further points out that considering the lack of knowledge of hygiene obtaining among a large proportion of these visitors, the wonder is that a serious outbreak has not already occurred. The writer referred to appears to dread the importation of diseases more than those which already prevail in Paris, and is of the opinion that an epidemic of bubonic plague is especially to be feared. While allowing that this note of warning is warranted by the situation, and that the danger from the outside is a real one which should be strictly guarded against, it may be doubted, after all, whether the chief menace to the health of "those on pleasure bent" will not be found in the sanitary conditions of Paris itself. For some considerable time typhoid fever has been unpleasantly active in the city on the Seine. In 1899 four thousand three hundred and twenty-nine cases of this malady were notified, of which number eight hundred and two proved fatal. A comparison of the reports of the first ten weeks of the years 1899 and 1900 can hardly be called reassuring. During that period last year three hundred and ninety-eight cases were notified, and in the corresponding period of the current year these figures have been more than doubled. As usual, when the matter was investigated the cause for this prevalence of enteric fever was discovered to be due to a contaminated water-supply. The affected districts were found to be those whose drinking-water is drawn from a stream named the Vanne. Observations made by Drs. Thoinot, A. J. Martin, and Miguel verified the suspicions that to the polluted water of the Vanne is due the increase of enteric fever in and about Paris.

For obvious reasons the Paris authorities and press have almost wholly ignored or discredited these reports. *Public Health*, touching on this point, says. "The specific bacillus is said to have been recognized and isolated from samples of the water taken from the river itself from a reservoir at Montsouris and from the supply of two army barracks, by several bacteriologists. Yet the prefect of the Seine tried recently to persuade the council that a mistake had been made by those who had examined the water, and that they had been misled. Other evidence, however, is too strong in incriminating the water of the Vanne, which seems liable to pollution from its source. Thus in that part of the town of Sens which is supplied with water by a branch taken from the main aqueduct of the Vanne enteric fever has appeared, while other parts of the town with a different supply have escaped." Under these circumstances it would be folly for visitors to Paris not to take certain precautionary measures, such as not to drink water unless they are satisfied that it has been boiled or efficiently filtered, and to use discretion in the consumption of raw vegetables and oysters which may have been washed or allowed to stand in unboiled water.

The American Association for the Advancement of Science.—At the closing session of the meeting of this association, which was held in this city the last week in June, the following officers were elected for the ensuing year: *President*, Prof. Charles Sedgwick Minot, of the Harvard University Medical School; *Permanent Secretary*, L. O. Howard, United States Department of Agriculture, Washington, D. C.; *General Secretary*, Prof. William Hallock, Columbia University; *Secretary of the Council*, D. T. McDougall, New York Botanical Garden; *Treasurer*, Prof. R. S. Woodward, of Columbia. The next annual meeting of the association will be held in Denver.

News of the Week.

Dr. William Moser has been appointed assistant visiting physician to the German Hospital, Brooklyn. Dr. Moser was formerly pathologist to the same institution.

Dr. Augustin H. Goelet writes that in his remarks reported in the MEDICAL RECORD of June 23d, p. 1,098, he advocated the use of morphine for the relief of severe pain, not of shock, following laparotomy.

The American Institute of Homœopathy.—The election of the officers of this society for the ensuing year resulted in the choice of Dr. A. B. Norton, of New York, for president, instead of Dr. W. W. Van Baun as announced last week. Dr. Norton and Dr. Van Baun were opposing candidates for the office of president, and the vote was 198 for Dr. Norton to 70 for Dr. Van Baun.

American Medical Editors' Association.—At the annual meeting of this association, held in Atlantic City, June 4th, the following officers were elected for the ensuing year: *President*, Dr. Alexander Stone, of St. Paul; *Vice-President*, Dr. Charles F. Taylor, of Philadelphia; *Treasurer*, Dr. S. W. Kelley, of Cleveland; *Secretary*, Dr. O. F. Ball, of St. Louis. The next meeting of the association will be held at St. Paul in June, 1901.

The Study of Mosquitos.—Dr. W. N. Berkeley, 121 East Twenty-sixth Street, writes that he is anxious during the coming three months to determine as fully as possible the various species of mosquito to which the malaria endemic in our locality may be due. Without the help of physicians practising in the near-by towns the difficulties of the work will be almost insuperable, and he therefore requests that physicians having patients with malaria notify him in order that he may, with the patients' consent, send a properly qualified man to collect mosquitos in houses and premises where fresh cases have developed.

The Thirteenth International Medical Congress.—The following is the programme of entertainments to be given during the session of the International Congress in Paris: On August 2d, the day of the opening of the congress, the president of the municipal council will give a reception to the members in the name of the French government. The following day a reception will be given by the president of the congress. On August 5th the president of the French republic will receive the members of the congress at the Elysée Palace. On August 7th a reception will be given by the municipal council of Paris in the grand hall of the Hôtel de Ville. On the evening of August 8th there will be a fête in the palace and garden of the Luxembourg, given by the committee on organization in honor of the members of the congress. Special entertainments will also be provided for the members of the different sections. Invitations for all these fêtes will be extended to the ladies accompanying the members of the congress, and there will also be a special committee of ladies who will look after the comfort and pleasure of the families of the members. There will be special rooms for the convenience of the ladies in one of the buildings of the Faculté de Médecine.

The New York School of Clinical Medicine has been closed. This action was decided upon by the medical board at a recent meeting, in consequence, it is said, of a disagreement with the board of trustees of the institution. It is possible, however, that the school will reopen in the autumn under different management.

St. John's Guild.—The Seaside Hospital at New Dorp, Staten Island, is open for the reception and care of sick children and their mothers. Until the floating hospitals are put in commission the patients will be conveyed to the hospital free of cost by the Staten Island ferry at 10 A.M. and 2:30 P.M., on which boats will be a nurse and orderly. Physicians may obtain tickets for distribution to their poor patients upon application at the office of the Guild, 501 Fifth Avenue.

The Plague in Rio de Janeiro, accounts of the outbreak of which are given in another column, has attained rather alarming proportions. On June 26th 25 new cases were officially reported, and the deaths numbered 12.—In Manila the total number of plague cases reported during April was 53. Of these 38 were certified by the medical officers to be genuine cases of the disease (29 Chinese and 9 Filipinos), while 15 were declared not to be plague. For the preceding three months the number of cases certified as plague was 195 (134 Chinese and 61 Filipinos) out of 212 reported, leaving 17 which were declared not to be cases of plague. Of the 195 plague patients, 150 died.

Quarantine Service in Cuba.—The President has recently signed an order systematizing the quarantine service in the island, and providing that, beginning July 15th, a commissioned officer of the Marine-Hospital service shall be detailed on the staff of the military governor of Cuba, as chief of the quarantine service of the island. Estimates of expenditures for the service and auditing of accounts will be under the supervision of the military governor, while the enforcement of the treasury quarantine regulations and details of officers remain as provided in the executive order of January 17, 1899. The chief quarantine officer of the Marine-Hospital service in Cuba, being on the staff of the military governor, will be able to establish a thorough co-operation in all the ports, and with the Marine-Hospital bureau in Washington, in enforcement of its regulations.

The British Medical Service in South Africa has recently been severely attacked in Parliament and in the newspapers, the allegation being that the sick and wounded had been neglected cruelly, and that their sufferings had been needlessly increased through mismanagement and insufficiency in the supplies. The medical staff was said to be inadequate, and houses which might have been utilized as hospi-

tals were occupied by officers. In reply to these criticisms, the parliamentary secretary of the War Office admitted that the allegations as to neglect of the sick and wounded were true to a lamentable extent. They were exposed, he said, to terrible hardships, but it was not due to any stinting of supplies, but to the insuperable difficulties of distributing those that had accumulated in South Africa. Every demand on the government in behalf of the troops, he said, had been complied with. The officials in South Africa said the hospitals had beds in excess of the demand. There were 5,000 beds in Natal and 13,600 in Cape Colony. There were in South Africa 466 army and 440 civilian medical officers and 556 female and 5,668 male nurses, besides the doctors and nurses engaged locally. The War Office, he said, had cabled Lord Roberts that disquieting reports regarding the hospitals were accumulating, and asked him if anything could be done, and particularly whether more nurses were needed. Lord Roberts replied that he did not wish to shirk responsibility or to screen the shortcomings of the medical corps, and he suggested a committee of inquiry. He said there had been an abnormal number of sick at Bloemfontein, due to the exhausting nature of the march and the terribly unsanitary condition of the camp at Paardeberg, where the only water available for drinking flowed from the Boer camp, higher up, where the river was crowded with decomposing animals, and to this number had been added many wounded after the fight on March 10th. To improvise accommodations at Bloemfontein for such a number, which had become two thousand before he left there, was no easy task. No tents were carried, and the public buildings had to be turned into hospitals. In three months there had been 6,369 admissions to the hospital of patients suffering from enteric fever, while the deaths numbered 1,370, about twenty-one per cent. Lord Roberts observed that he did not know whether this would be an abnormal rate in civil hospitals in peace times, but if it were, it was due to the exhausted state of the men and not to the neglect of the medical corps. The strictures on the efficiency of the army medical service were evidently made by amateur critics who seem to think it is as easy to provide for the comfort of a body of troops in an enemy's country as for a party of Cook's tourists, and who never think that a vast amount of suffering is inseparable from the rapid march of a constantly fighting army.

Cuban Sanitary Ideas.—Several Cuban newspapers of the baser sort, when other occasions for fault-finding fail, accuse the American government of extravagance in carrying out the various sanitary reforms which have been instituted. The writers share Svengali's amused horror at the waste of so much good water in bathing, and deprecate the expenditure of so much time and labor in preventing the reaccumulation of the mountains of filth which formerly blocked the streets of their towns. *El Cubano* recently revealed one of the reasons for this opposition. The Cubans, it said, justly and properly object to the expenditure of such a large proportion of the revenues of the island in measures intended to repress yellow fever, for the only result of such measures is to protect the lives of the Americans, since the Cubans themselves are immune from yellow fever. The editor of *El Cubano* is evidently a man of broad views and unselfish ideals who ought to be made president of the first Cuban antivaccination society.

A Medical Book Thief.—A Boston physician, a graduate in medicine of McGill University in 1833, has been convicted on his own confession of stealing book plates from the library of Harvard University. His case has been continued to the next term of the court for sentence.

Award of Prizes at the College of Physicians and Surgeons.—At the recent commencement of Columbia University, Dr. August Jerome Lartigau was awarded the Alonzo Clark scholarship, Dr. James D. Voorhees the Stevens triennial prize, and Dr. David Bovaird, Jr., the Alumni Association prize of the College of Physicians and Surgeons.

Cholera in India.—A despatch from Bombay, dated July 3d, says cholera prevails to an unusual degree in the entire Bombay Presidency with the exception of three districts. The cases reported for the week ending June 26th numbered 20,689, and the deaths during the same period 12,333.

Physicians Saved from Burning.—The surgeons of the three North German Lloyd steamers, burned on Saturday last at the Hoboken dock fire, were all saved. They were Drs. Leuthe of the *Bremen*, Staby of the *Saale*, and Brauns of the *Main*. They sailed on the *Kaiser Wilhelm der Grosse* on Tuesday.

The Celtic Medical Society.—At a regular meeting of the Celtic Medical Society of New York, held recently, the following officers were elected for the ensuing year: *President*, Dr. John J. Morrissey; *Vice-President*, Dr. William J. Farrell; *Secretary*, Dr. J. J. Cronin; *Treasurer*, Dr. M. C. O'Brien.

A Hospital Romance.—That truth is not less strange than fiction is illustrated by a recent occurrence at the Philadelphia Hospital. Some two years ago a woman was found on the street in a demented and destitute condition, and was sent to the hospital. She could not give her name or any information as to where she had come from. For a long time there was no improvement, but after eighteen months the woman was able to relate something about herself and her family. Her husband was communicated with, and as a result her son came from a distant city to take her home. It turned out that she had disappeared five years before, and large sums of money had been spent in the search for her.

The County Association Officially Recognized.—The New York County Medical Association has won a suit brought to compel the city to pay it a penalty of $50 secured by the prosecution of a person practising as a physician without a license. The association furnished the proof on which the man was convicted, but the fine of $50 was paid into the city treasury.

The association contended that the law of 1895 provides that when the complainant in such cases is a State medical society or a county medical society entitled to representation in a State society, such fines shall be paid to the complainant. The city took the position that the act referred to the Medical Society of the County of New York. The court decided, however, that the association is entitled to representation in the New York State Medical Association, which is a legally organized society in affiliation with the American Medical Association, and that therefore it must have the money as provided in the law of 1895.

Dr. Jameson, who has passed successfully two or three medical examinations, led a body of raiders into the Transvaal, been imprisoned therefor in South Africa and in England, suffered from a severe attack of typhoid fever while besieged in Kimberly, and has had other adventures of various sorts, has now been elected unanimously a member of the Cape parliament from Kimberly.

The International Congress of Medical Electrology and Radiology.—The principal railways of France announce a reduction of fifty per cent. in rates for the members of this congress, and the Italian roads will allow a reduction of from thirty to fifty per cent., according to the distance. The membership cards will give the right of free entrance to the Exposition during the session of the congress.

Tuberculosis in the Schools.—The board of education of Honolulu has adopted a resolution prohibiting any one from teaching in the public schools who is suffering from tuberculosis or other contagious or infectious diseases, and also prohibiting children afflicted with such diseases from attending the schools. It is said that there has been a great influx of consumptives to the islands during the past year, the attraction being the mild climate, and the health authorities have become alarmed for the safety of the susceptible native population.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending June 30, 1900. June 22d.—Assistant Surgeon C. N. Fiske ordered to the Boston navy yard. June 23d.—Surgeon W. H. Rush, when discharged from treatment at the naval hospital, Mare Island, Cal., ordered to Washington, D. C., July 10th, for examination for retirement, and then home and to await orders. Assistant Surgeon O. M. Eakins detached from the *Buffalo* and ordered to the *Scindia*. June 26th.—Surgeon C. F. Stokes promoted to surgeon from May 31, 1900.

The Late Dr. Landon Carter Gray.—The following resolutions upon the death of Dr. Landon Carter Gray were passed at a meeting of the medical board of the St. Mark's Hospital, held June 23, 1900:

"*Whereas*, The medical board of the St. Mark's Hospital has heard with profound sorrow of the death of their colleague and consulting-physician, Dr. Landon Carter Gray, which occurred on May 8, 1900;

"*Whereas*, Dr. Landon Carter Gray was an esteemed member by reason of his broad knowledge of medicine and his rare talents in neurology; he was a kind friend to many and especially cordial in his relations with the younger members of the profession: therefore be it

"*Resolved*, That the members of the board hereby express their great grief at the removal of their esteemed colleague by death, and extend their sympathy to the widow, relatives, and friends of the deceased.

"*Resolved*, That a copy of this tribute to the memory of Dr. Landon Carter Gray shall be spread on the minutes of this board and a copy thereof be sent to the family."

CARL BECK, M.D., president; IGNATZ MORVAY ROTTENBERG, M.D., secretary.

The Late Dr. William Pierson.—The following resolutions were adopted by the staff of the Orange Memorial Hospital on June 13, 1900:

"*Whereas*, It has pleased the Master to take from us our friend and chief of staff, William Pierson, M.D.; and

"*Whereas*, We, the medical staff of the Orange Memorial Hospital, in special meeting assembled, wishing to make known to all our feeling of deep grief caused by his death, do hereby

"*Resolve*, That a suitable memorial be prepared and presented to his bereaved family expressive of our sympathy and of our own loss; and

"*Resolve*, That the staff will attend the funeral in a body; and that these resolutions shall be printed in the medical and secular press, and transcribed upon the records of the staff of the Orange Memorial Hospital."

Obituary Notes.—DR. GEORGE S. WARD, of Newark, N. J., died on June 26th of pulmonary trouble. He was born in Bloomfield, N. J., in 1827, and was graduated from the College of Physicians and Surgeons, New York, in 1849. He retired from active practice many years ago.

DR. KING WYLLY, of Savannah, Ga., died of apoplexy on June 24th, in Saratoga, N. Y. He was fifty-nine years old, and was a graduate of the medical department of the University of Virginia in 1869.

DR. BENNETT BUSSEY, the oldest physician in California, died at his home in Biggs, on June 24th, at the age of ninety-three years. He was graduated from the medical school of the University of Maryland April 7, 1828. He went to California in 1876.

DR. HOWARD P. BALLIET, of Philadelphia, twenty-three years old, a recent graduate of the medical department of the University of Pennsylvania, was drowned at Atlantic City on June 25th.

DR. FREDERICK MAY FOSTER died in Kingston, Ohio, on May 19th, at the age of twenty-five years. He was a graduate of the Ohio Medical College in 1899, and had just completed his term of service as interne at the Protestant Hospital of Columbus.

DR. LOUIS ARCULARIUS died at his home in this city on July 1st of apoplexy. He was born in Hessen, Germany, in 1838, and came to this country almost immediately after graduation from the University of Giessen, in 1867.

Progress of Medical Science.

New York Medical Journal, June 30, 1900.

The Laryngeal Manifestations of Typhoid Fever. — L. B. Lockard reviews the literature of the subject, and describes the case of a man of thirty-five years who in the sixth week of the disease presented an abscess of the left arytenoid. Owing to threatened suffocation, tracheotomy was performed, followed by endolaryngeal incision of the tumor, and the evacuation of a considerable amount of pus. After recovery the left vocal cord was found fixed in adduction, due to ankylosis of the crico-arytenoidal articulation. The right cord was abducted and perfectly rigid, due, no doubt, to a perichondritis that had extended across the median line. After all signs of inflammation had disappeared dilatation was daily performed and continued for a long time. The cords readily separated, but upon withdrawal of the instrument would immediately fall back into their old positions. The tracheal cannula was constantly worn except when the patient was at rest. In order to make its removal possible the cords were taken away piecemeal by the double curette of Heryng, and an opening was made sufficiently large to permit free breathing.

The Closure of a Cleft Palate by Lingual Implantation.— In a case of cleft palate in which the Langenbeck as well as the Davies-Colley operation failed to cover the immense congenital defect, Carl Beck recently implanted a portion of the tongue. The ease with which even extensive resection of the tongue is tolerated by carcinomatous patients induced him to form a lateral flap from the tongue, which, after being turned and reflected near the base, was united with the freshened edge of the cleft of the same side. The gaping wound margins of the side of the tongue were then accurately united, and the floor of the mouth and the lingual angle were packed with iodoform gauze. During the after-treatment a mild solution of boric acid was sprayed through the nostrils every fifteen minutes. Liquid diet was given exclusively. After nine days the basis of the flap was severed, and one week later the flap was united with the opposite margin of the cleft according to the usual uranoplastic procedures.

A Contribution to the Study of Influenza in Children, with Special Reference to its Treatment with Sodium Benzoate.— H. B. Sheffield gives a general review of the subject and appends a lengthy bibliography. Concerning treatment he says that he has found sodium benzoate to relieve all symptoms within forty-eight hours. For high temperature he occasionally gives a little acetanilid, which also relieves pain, adding, when the latter is severe a little codeine. When rheumatoid pains predominate, he combines salol with the foregoing. In connection with internal remedies he uses the compound tincture of benzoin for inhalation, regarding it as an admirable respiratory antiseptic, expectorant, and anti-spasmodic.

The Rôle of Purulent Rhinitis of Childhood in the Production of Atrophic Rhinitis.—R. McKinney gives the clinical histories which bear out the truth of Bosworth's dictum as to the causative relation of the early purulent rhinitis of children to the later atrophic condition so frequently found. McKinney is not disposed, however, to believe that this relation of cause and effect invariably holds.

Formalin as an Antiseptic in General Surgery, Gynæcology, and Obstetrics.—By G. E. Crawford.

Are there Veritable Valves in the Rectum?—By W. Bodenhamer.

The Treatment of Puerperal Infection.—By J. B. Killebrew.

The Medical News, June 30, 1900.

When is it Proper to Interfere in Apparently Difficult or Delayed Cases of Labor, Especially in Primiparæ?—Malcolm McLean directs attention to the fact that a woman bearing her first child is, for reasons peculiar to her class, particularly liable to certain difficulties and dangers, which seldom menace the woman who has before gone through the normal stages of labor. Since malpresentations and malpositions of the child, and deformities of the bony pelvis of the mother, may obtain in the case of the multipara as in that of the primipara, the conclusion is obvious that the peculiar danger menacing the latter resides in the condition of the soft structures of the parturient canal. The difference between the primipara and the multipara in this respect is to be found in the fact that in the primipara that peculiar, physiological softening down and relaxation of the soft parts, which should precede the passage of the child, goes on generally very slowly, occupying many more hours in its accomplishment than in the case of the multipara. The deduction which the author draws from this fact is that it is meddlesome midwifery to interfere too early in the course of a first labor. He holds that, if the presenting part is high up and movable, if the pelvic measurements are within normal limits, the soft parts unrelaxed and not œdematous or swollen, the case may be and should be allowed to proceed without interference. When the forces are apparently normal and the presenting part is arrested at any given point for over half an hour, or if the soft parts of the mother, having once been relaxed and thoroughly moistened with mucus, are becoming hot, œdematous, and discolored, the indications are for early assistance.

The Prevention of Dystocia due to Fœtal and Pelvic Disproportion.—By Edward A. Ayers.

The Treatment of Tumors Complicating Pregnancy.—By Brooks H. Wells.

Boston Medical and Surgical Journal, June 28, 1900.

A Study of Twenty-Four Cases of Typhoid Fever with Symptoms of Peritoneal Infection. Laparotomy.—George B. Shattuck, J. Collins Warren, and Farrar Cobb, a committee of the Boston Society for Medical Improvement, report upon these cases, seventeen of which were cases of perforation of the bowel, two of preperforative necrotic areas, one of ruptured mesenteric gland, one of general septic peritonitis, the cause of which was not clear, and three were cases in which symptoms of intra-abdominal infection existed, but in which no cause for the symptoms could be discovered at operation. Of the three cases last mentioned, recovery occurred in two, and of the remaining twenty-one, in which peritoneal infection was found at operation, recovery occurred in three. From a study of these cases the committee concludes that (1) in many very sick patients perforation or peritoneal infection cannot be diagnosed until the results are already widespread and of fatal extent. The chances of a fatal issue from an abdominal operation in such cases are overwhelming. (2) In mild cases of fair general condition an abdominal operation is readily borne, provided no peritoneal infection is present. (3) A small number of mild cases may have sudden perforation with free extravasation. In these the symptoms are fulminant, but localized to a great extent, and in these (4) operation must be done at once, for general infection may become past relief in from one to five hours, and walling off of the perforation by protecting adhesions is so rare as not to be counted upon. (5) In the majority of mild cases, beginning infection (whether from perforation or not) is marked by comparatively slight symptoms—local pain, tenderness, spasm, and leucocytosis. The severe following symptoms mean general peritonitis. (6) These warning symptoms demand serious consideration and study, but in many cases are either not rightly understood or not acted upon. (7) Complaint of abdominal pain in a case of typhoid fever should always lead to a suspicion of beginning peritoneal infection. (8) Frequent leucocyte counts are needed in every case. In the presence of abdominal pain an hourly count is necessary. (9) Pain associated with local tenderness and a muscular spasm and a rising white blood count indicates in most cases an operation.

Separation of the Epiphysis of the Olecranon.—By F. J. Cotton.

A Modification of the Sphygmograph.—By Robert T. Edes.

Journal of the American Medical Ass'n, June 30, 1900.

Intracranial Pressure.—W. N. Bullard calls attention to certain non-traumatic conditions, without localizing symptoms, in which operation is useful. After giving cases, he concludes: (1) There exist certain non-traumatic cases of increased intracranial pressure of unknown or doubtful origin. (2) Whenever such an excess of intracranial pressure exists as to cause serious symptoms, the question of its relief by opening the cranium and cutting the dura should always be considered. (3) In certain non-traumatic cases of excess of intracranial pressure, more or less permanent relief—or even cure—may be obtained by proper surgical interference. (4) In case of acute severe optic neuritis of unknown origin, the question of opening the cranium and relieving the excessive intracranial pressure should be considered.

Abdominal vs. Vaginal Hysterectomy for Uterine Carcinoma.—J. B. Deaver favors abdominal hysterectomy for the great majority of cases of uterine carcinoma, though in some instances the vaginal route may be better. The advantages are completeness of operation, removal of pelvic glands, better area for complete extirpation of carcinomatous tissue, lessened danger to the uterus and of infecting the peritoneum, and less risk of hemorrhage.

Typhoid Fever.—J. H. Sackrider says the indications for treatment are not always alike. Since 1897 he has used cold water internally as an enema to reduce temperature,

at the same time spraying the skin. Cases are cited. Cold enemata relieve sleeplessness and restlessness. Early antisepsis of the gastro-intestinal tract is greatly to be desired.

Hemorrhage after Confinement and its Treatment.—By Herman E. Hayd.

The Philadelphia Medical Journal, June 30, 1900.

A New Pathogenic Mould.—W. Ophüls and Herbert C. Moffitt report the case of a farm laborer, nineteen years old, who died after suffering from pleural effusion, inflammatory joint swellings, cough, constantly elevated temperature, slight chills, and profuse sweating. The diagnosis was septico-pyæmia. At the autopsy numerous abscesses were found in various parts of the body, in the pus of which were present peculiar parasitic organisms which in similar recorded cases have been described as protozoa—coccidioides inmitis pyogenes. In cultures of these organisms a mould developed on the second day. A pure culture of this mould in the third generation was injected into the ear-vein of a rabbit. The animal showed no symptoms and was killed three weeks after the inoculation. Tubercle-like nodules were found in the lungs, spleen, and kidneys, and in them the protozoon-like bodies were seen, but no mycelium. The authors therefore conclude that the protozoon-like bodies and the mycelium are different stages in the development of the same fungus. The relation between the mould and protozoon-like bodies, they think, is that the latter are a form of fructification of the mould. The way in which they develop from the mould after injection into the animal body remains to be studied.

Especial Hospitals for Consumption among the Poor in Our Cities.—By Edward O. Otis.

Questions of the Day in Medicine.—By J. M. Da Costa.

Angina Pectoris.—By Clifford Allbutt.

The Lancet, June 23, 1900.

A Plea for Early Operation in Cases of Undoubted Tubercle of the Lung.—In discussing the dangers of operation in cases of this nature, J. F. Palmer finds three to be especially noteworthy: first, pneumothorax; second, surgical emphysema; third, hemorrhage. Emphysema may result from rupture of the trachea or larger bronchial tubes, external wounds into the cellular tissues surrounding the costal pleura without lesion of the latter, lesion of the costal pleura only with external wound, and lesions of both pleuræ with or without external wound. In regard to hemorrhage, the writer says that when a cutting operation is required at the apex of the lung, and no adhesions are present, the diseased part, if not too extensive, might be included in a single ligature and the whole excised. In all operations on the lung the introduction of bacteria from without, through the wound in the chest-wall, can be effectually prevented by modern antiseptic methods. But there is in these cases another channel of entrance for bacteria, viz., the trachea and bronchial tubes. The general experience of internal wounds of the lung when the skin is intact points to the pneumococcus as most to be feared in this direction. Pneumonia is the most frequent complication of rupture of the lung and the wounds caused by fractured ribs, injuries in which the trachea is the only passage for microbes, and which resemble in this respect operations on the lung with the external opening in the chest wall hermetically sealed.

Acroparæsthesia.—Three cases of this affection are described by F. H. Edgeworth. The common feature was a dead, tingling feeling in the hands and arms, either at night or on using the hands, or persistent, though much worse on manual labor. No objective sign could be found in any of the cases. The pathology of acroparæsthesia is unknown. According to Lereboullet the fault lies in the peripheral venous circulation, which, by producing ischæmia, or it may be passive hyperæmia, results in serous infiltration of the terminal branches of the nerves. And certainly in some instances objective signs of vasomotor disturbance have been noted. But this theory would cover at most a few only of the recorded cases, and does not, for instance, explain those described above in which no vasomotor changes were apparent. The origin of the disease is probably to be found in the age and sex of the patients, and the affection may be related to those other abnormal actions of the central nervous system which are so apt to occur in women during the years preceding and following the menopause. The diagnosis should be based on the conjunction of these abnormal sensations with an absence or insignificance of signs of vasomotor disturbance. The affections with which acroparæsthesia is most likely to be confounded are hysteria, peripheral neuritis, erythromelalgia, acrocyanosis, acromegaly, and arterial degeneration.

Some Notes on the Introduction and Spread of Plague.—From a personal experience in Bombay and Calcutta G. J. Blackmore discusses the possibility of the invasion of England by the dreaded disease. He believes that if the plague is to be prevented from entering the mother country there must be (1) a most careful search made for modified cases of plague for some considerable time after the disease has apparently died out in places that have been attacked by it; (2) rigid inspection of vessels and passengers coming from infected places, not only while they are known to be infected but for months afterward; (3) disinfection of dirty clothing and rags coming from such places; (4) a sharp lookout kept for any increased mortality among rats in seaport towns, with repeated search for the plague bacillus in the bodies of those found dead; (5) an attempt made to exterminate the vermin which may act as carriers of the plague; and (6) early inoculation of the people when plague has appeared among rats.

On Chylous Ascites, with an Illustrative Case.—The patient of J. H. Croom was a woman aged thirty-nine years, with abdominal swelling and gradual weakness and emaciation. On deep palpation several hard masses could be felt in the abdominal and epigastric regions. The diagnosis was cancer of the omentum and mesentery. Later the abdomen was aspirated and the fluid found to be essentially finely emulsified fat with much granular fatty débris. Death resulted in about two months after admission to hospital. The autopsy showed diffuse cancerous masses at different points in the abdomen. Especially marked was the malignant infiltration in the neighborhood of the receptaculum.

On the Degeneration of the Neuron.—First Croonian lecture, by W. Mott.

Differentiation in Diabetes.—By F. W. Pavy.

British Medical Journal, June 23, 1900.

A Case of Hemorrhagic Pancreatitis.—J. C. Uhthoff and E. F. Maynard relate the case of a man seventy-seven years old, who had recently complained of "indigestion." The morning before admission he was suddenly seized with abdominal pain, followed by sickness and collapse. Coffee-ground matter was vomited until death, three days later. The head of the pancreas was dark and the size of an orange. The entire organ was firmly adherent to adjacent structures. Spots of fat necrosis were scattered in it. There was one large hemorrhage in the head of the gland and smaller ones throughout.

Epidemic Cerebro-Spinal Meningitis in Dublin.—A. R. Parsons and H. E. Littledale report an outbreak in Ireland, which had been free from the epidemic form since 1886. The records of cases seen at the Dublin Hospital are given with pathological reports. The diplococcus as described by Weichselbaum was found, and kept alive by transplanting it on Loeffler's serum every three or four days, keeping it constantly at 37° C.

Acute Pancreatitis Complicating Mumps.—H. W. Jacob gives notes of a case of this rare complication of parotitis. Vomiting of severe nature was seen in a boy of ten years, followed by violent pain in the upper abdomen, and an enlarged pancreas was made out. One week later all tenderness had disappeared. The parotitis subsided as the pancreatic affection developed.

The Croonian Lectures on Degeneration of the Neuron.—By Frederick W. Mott.

General Emphysema Complicating Fractured Ribs.—By J. F. Heise Ellerton.

Two Lectures on Antenatal Diagnosis.—By J. W. Ballantyne.

Berliner klinische Wochenschrift, June 11, 1900.

Epidemiological Contribution to the Question of Malaria Infection.—E. Grawitz alludes to the mosquito-infection theory, and then gives statistics of the amount of malaria occurring during given periods in certain divisions of the German army. His figures show that the greatest amount of malaria did not occur during those months when the mosquitos are most active and liable to sting, but cases of the fever were more numerous in the spring. He expresses

the view that there are other organisms than the mosquito which may be the intermediate host of the malarial parasite, particularly those which live in water, and therefore calls attention to the necessity of a water-supply above reproach in our efforts to eradicate malaria.

The After-Treatment of Operations on the Eyeball.—G. Gutman describes the technical procedures followed by him in operations of this class, with special reference to the application of bandages and the kind to be preferred.

Typhoid Fever.—By Th. Rumpf.

French Journals.

Phthisiotherapy.—Letulle discusses the cure of phthisis by alimentation in hospital practice. "The kitchen is the best pharmacy of the lungs" is a saying which cannot be too often repeated. It is likewise the cheapest form of treatment. The mode of carrying out the plan with menus for different meals, and results, are given. The following practical conclusions are drawn: (1) The cure by food in hospital practice is easy, cheap, and often most favorable, whatever may be the stage of the disease. (2) Young tuberculous subjects benefit most from the hygienic hospital course. (3) Increase in weight is shown especially during the first four or six weeks after admission to the hospital. (4) When there is a stationary period after an increase, the patient should be sent to the country, the hospital having done all it can in the case. (5) Male patients seem to benefit more than female from the hospital food cure.—*La Presse Médicale*, June 16, 1900.

Some Clinical Contributions to the Disease Called Malta Fever.—Edmond Neusser describes this affection, which infects the borders of the Mediterranean, the Red Sea, and many islands including Porto Rico. It begins with headache, pains in the extremities and lumbar regions, insomnia, lack of appetite, vomiting, and constipation. Sweating is so profuse that the acute attack has been termed febris sudoralis. The chronic course has been called phthisis Mediterranea. The febrile attack has a duration of one to five weeks. The mortality is one to two per cent. Recurrences may give a course of many months and even of several years. Neusser showed at the Wiesbaden congress a subject of Malta fever sick for eight years. This disease has a great importance for armies, since in the attack a soldier loses about three months' time.—*Le Progrès Médical*, June 16, 1900.

The Geographical Distribution of Goitre in France.—L. Mayet, in calculating the mean coefficient of each department for a period of years, obtained the proportion of young men classed in the auxiliary service of the army for goitre. This number of goitre cases in each thousand examinations gave the coefficient of the actual frequency in each department. Six departments gave from ten to forty-five goitrous subjects of twenty years of age in one thousand examined. In eleven departments goitre appears to have no existence. Between these two extremes are four series having from ten in one thousand down to 0.50 to 1.25 in one thousand. For the whole of France goitre appears to have diminished, while on the increase in certain regions.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 14, 1900.

Erythema Scarlatiniforme.—Breton records an instance of scarlatina-like rash due to subcutaneous injections of cacodylate of sodium given to a man thirty-eight years of age, as a cure for phthisis. During the night succeeding an injection there are general malaise, heat, and irritation of the skin preventing sleep, and followed by itching. The erythema is generalized in from twelve to fourteen hours from the time of injection, and is most marked over zones of pressure. There is no fever. Thirty-six hours later the erythema grows pale and disappears on the third day, and is not followed by desquamation.—*Gazette des Hôpitaux*, June 19, 1900.

Botryomycosis.—Xavier Delorè refers to a case recently reported by him as occurring on the ulnar border of the hand. He now adds another from the service of Professor Poncet, in which the tumor was located on the right little finger near the insertion of the nail. The vascular pedunculated tumor of pea-size was excised, and no recurrence took place. The infection had undoubtedly occurred in caring for horses.—*Gazette des Hôpitaux*, June 12, 1900.

University Medical Magazine, June, 1900.

Two Cases of General Anæsthesia.—C. W. Burr finds anæsthesia of the whole surface rare, even in hysteria. The two cases illustrate the fact that, besides hysteria, evidences of organic disease may be found. In the hysterical case a man aged twenty-four years had for eleven months numbness and tingling in the legs, with gradual loss of power. He became suddenly unconscious, and remained so for two or three days. On regaining his senses he was paralyzed in both legs, and had incontinence of urine and fæces. This lasted for six months. Subsequently there was complete anæsthesia to touch, pain, and temperature over the entire body. There were attacks of unconsciousness, followed by hysterical manifestations, and once the temperature reached 112 F. The second case was that of an unmarried woman aged twenty-eight years. At the age of five, after a fright, she began to stagger and became unable to walk. In about a year she rapidly became blind. After two years following convulsions she became deaf in the left ear and insensitive on the left side. Nine years ago, after serious illness and convulsions, she became insensitive on the right side, and partially deaf in the right ear. The movement of the limbs is awkward, and when placed on her feet she stands for a few minutes and then sinks to the floor. There is complete anæsthesia to touch, pain, and temperature over the entire body, with loss of the senses of taste, smell, and touch, and roots of teeth can be extracted without pain. It would appear that early in life there had been some organic brain disease.

Observations of Blood Changes following Cœliotomy.—C. Y. White has pursued studies to determine whether the blood showed a reaction to major gynæcological operations. The average leucocyte count on the hospital chart is useless. The blood examination should be considered only in connection with a thorough examination of the patient. In the early stages of malignant disease slight changes or none may be found; later the picture is variable, and in the cachectic stage we may have profound secondary anæmia with or without leucocytosis. The leucocytes are studied before and after operation and in the complications during convalescence. A series of tables shows the results obtained.

Acute Enlargement of the Thyroid Gland, with Report of Cases.—Alfred Stengel refers to enlargement of the gland from fright, emotional disturbances, menstruation, eroticism, etc. Acute inflammatory enlargement may be due to traumatism, pressure, possibly cold, and infection (diphtheria, scarlatina, hereditary syphilis, tuberculosis). The case reported was that of a boy aged seventeen years, whose swelling was of three weeks' duration. It was soft and elastic. The general symptoms resembled those of Graves' disease. Death finally occurred from asphyxia. Malignancy was suspected from the rapid course. The marked feature was the suddenness with which severe symptoms developed.

Historic and Practical Remarks on the Operative Treatment of Cancer of the Cervix.—By J. G Clark.

Prosthesis of the Jaw at Time of Operation.—By M. H. Cryer.

Report of Two Cases from the Neurological Service of the University Hospital.—By B. A. Anspach.

The Journal of Tropical Medicine, June, 1900.

Blackwater Fever.—David Kerr Cross, discussing this disease as it is seen in British Central Africa, says that it has not yet been definitely determined whether or not hæmoglobinuric fever is malarial fever in an exaggerated form. While there are marked similarities in the two affections, there are also marked differences. The similarities are: rigors, oscillations of temperature, sweating, and recurrences. The differences are: (1) Natives are immune; (2) many Europeans also enjoy complete immunity; (3) Europeans rarely take the disease, if at all, until they have been a year or two in the malarious country; (4) those subject to blackwater fever may have an ordinary malarial attack without bringing on hæmoglobinuria; (5) no European once subject to blackwater fever ever acquires an immunity from it; (6) even after the sufferer from blackwater fever has left the endemic area where he acquired the disease the affection is apt to recur, pointing to the likelihood of blackwater fever being due to some parasite peculiar to itself, lodged in the bone marrow, liver, spleen, or brain; (7) it appears to resist the action of quinine. The author distinguishes four forms—the paroxysmal, the regular, the typhoid, and the suppressionary. The three pathognomic physical signs of blackwater fever are: (1) the black or blood-red urine, (2) the development of yellow coloring-matter which invades every tissue of the body, and (3) melanin in the blood plasma or within the affected red blood corpuscles. We do not know what is the parasite of blackwater fever, for the plasmodium malariæ has not been seen in this affection. The treatment is symptomatic; quinine does no good and may do harm.

Upon the Part Played by Mosquitos in the Propagation of Malaria.—By George H. F. Nuttall.

Notes from South Africa.—By M. T. Yarr.

Reviews and Notices.

The Surgical Diseases of the Genito-Urinary Tract—Venereal and Sexual Diseases. A Text-book for Students and Practitioners. By G. Frank Lydston, M.D., Professor of the Surgical Diseases of the Genito-Urinary Organs and Syphilology in the Medical Department of the State University of Illinois, etc. Illustrated with 235 engravings. Philadelphia, New York, and Chicago: F. A. Davis & Co. 1899.

The author has written a work of over one thousand pages, and the type is not large. The subjects embraced are often presented separately, and either the "genito-urinary surgery" or the "sexual and venereal diseases" would make a volume by itself. With the exception of what the author is pleased to call "a few heresies of his own" there is not much that differs from the text-books presented from time to time for the use of students and practitioners. This work, as the author states, is not designed for the specialist, nor will the latter find much that he cannot get elsewhere. There are few of the very large number of illustrations which have much to recommend them especially. Some fall far short of elegance from an artistic standpoint, and, what is of greater importance, several fail to give an adequate idea of the conditions which they are intended to represent. In running over the pages the impression is not given of a profusely illustrated work, so many of the figures are small cuts of instruments, pathological specimens, etc., reproduced from other works. Not the least attractive feature of the work is that it is written in the author's characteristic free style and is pervaded by his personality.

Surgical Pathology and Therapeutics. By John Collins Warren, Professor of Surgery in Harvard University, Surgeon to the Massachusetts General Hospital. Illustrated. Second edition, with an appendix. Philadelphia: W. B. Saunders. 1900.

The chief additions in this edition have been placed in an appendix, which contains an enumeration of the scientific aids to surgical diagnosis, together with a series of sections of regional bacteriology. Besides this, a new chapter on antiseptic surgery has been added. An important feature of this work is the aid it furnishes to the specialist in various departments. The sections on "regional bacteriology" are not alone of interest, but are of decided importance, coupled as are the descriptions of the findings with principles of treatment drawn from the latest teachings of those having authority to speak. The illustrations are generally above the average.

International Clinics. Edited by Judson Daland, M.D., Instructor in Clinical Medicine in the University of Pennsylvania, etc. Vol. IV., Ninth series, 1900. Philadelphia: J. B. Lippincott Company. 1900.

There are thirty-seven generally well-known names among the present contributors, and their articles are illustrated with twenty-one drawings. As usual, the reading-matter is of a rather high order. This quarterly of clinical lectures on various branches of medicine and surgery now contains specially prepared articles on treatment and drugs by professors and lecturers in the leading medical colleges.

The American Year Book of Medicine and Surgery. Under the general editorial charge of George M. Gould, M.D. Philadelphia: W. B. Saunders. 1900.

This yearly digest of scientific progress and opinion in all branches of medicine and surgery, drawn from journals, monographs, and text-books foreign and American, has this year been divided so that the subscriber receives two volumes—one on surgery, the other on medicine. This is an excellent plan. The original volume was altogether too ponderous. Changes in the editorial staff include the new names of Drs. David Reisman, R. W. Wilcox, A. A. Stevens, Reid Hunt, and Walter Jones. The number of coworkers has fallen from twenty-eight to fifteen. The subject-matter comprises the usual quantity and quality of abstracts, with critical editorial comment covering the various branches.

Gynæcology: A Manual for Students and Practitioners. By Montgomery A. Crockett, Adjunct Professor of Obstetrics and Clinical Gynæcology, Medical Department University of Buffalo, etc. Series edited by Bern B. Gallaudet, M.D. Illustrated with 107 engravings. Philadelphia and New York: Lea Brothers & Co.

This addition to the red-covered series of pocket text-books put out by this well-known house fills the requirements of essential feature in moderate compass. It is not alone an *exposé* of the author's views and experience which one reads, but a *résumé* of what many recognized writers and teachers have given the world. However, the writer's personality stands out, making the subject-matter much more than a compilation.

Nervous and Mental Diseases: A Manual for Students and Practitioners. By Charles S. Potts, M.D., Instructor in Nervous Diseases, University of Pennsylvania, Assistant Neurologist to the University Hospital, etc. Philadelphia and New York: Lea Brothers & Co.

This is another of the above-mentioned series illustrated with eighty-eight engravings. Such matter as is deemed necessary for the student's requirements is here presented, exception being made in the matter of anatomy of the nervous system. Naturally, larger text-books will have to be consulted for an exhaustive knowledge of any subject. The therapy has been presented in such a way that it will be useful as well to the practitioner. Methods of examination have received considerable attention.

Diseases of the Intestines. By Max Einhorn, M.D., Professor of Medicine at the New York Post-Graduate Medical School and Hospital, etc. Pp. 391. New York: William Wood & Company. 1900.

This treatise is offered to the profession as a continuation of the author's work on "Diseases of the Stomach," and as in that book, so here also, practical points in diagnosis and treatment are always placed in the foreground. After a short account of the anatomy and physiology of the intestines, there follows a careful description of the methods of examination and treatment, especial attention being paid to the microscopical examination of the fæces. Acute and chronic intestinal catarrh and dysentery are treated of in separate chapters. The writer gives a good description of the symptoms of intestinal ulcers, and a very readable description of carcinoma of the bowel. The chapter on hemorrhoids is very complete, and in the chapter on appendicitis the author gives a good summary of the indications for surgical interference in this disease. Acute and chronic obstruction, diarrhœa, constipation, nervous affections of the bowel, and intestinal parasites are treated of in some detail. We believe that the book will be of value and practical utility to the practitioner, and will fully accomplish the aim of the author—to give to the physician a short, practical, and useful reference book on intestinal diseases.

The Irrigation Treatment of Gonorrhœa: Its Local Complications and Sequelæ. By Ferd. C. Valentine, M.D., Professor of Genito-Urinary Diseases, New York School of Clinical Medicine; Genito-Urinary Surgeon, West Side German Dispensary. New York: William Wood & Compay. 1900.

This is one of the class of books, unfortunately only too rare in medicine, written by one who combines with a knowledge of his subject the art of expressing his meaning in easily comprehensible language. It is intended more particularly for the general practitioner, who must treat gonorrhœa along with all the other ills of suffering humanity, and who wishes to do so in some more effective way than by filling the stomach with a nauseous mixture of balsams and oils. As is set forth in the title, the treatment here expounded is that by irrigation—a treatment which is as rational in theory as it is efficacious in practice. In addition to the details of simple irrigation, the advantages of dilatation and irrigation in chronic cases are dwelt upon, and the methods of procedure in such cases are minutely and most clearly described. But the book is by no means a treatise on irrigation of the urethra only—it is rather a complete guide to the management of gonorrhœa in all its forms and complications and of the sequelæ of the disease. The means of locating foci of disease in uncured cases are referred to at sufficient length, as are also the various steps in the performance of circumcision and other multitudinous details in the cure of a case of gonorrhœa. The work is illustrated by fifty-seven engravings, mostly drawn from actual scenes in office work, which add greatly to the value of the book as an aid in every-day practice.

Traité pratique des Maladies des Pays Chauds et Tropicaux. Par le Docteur J. Brault, ex-Médecin-Major de l'Armée, Professeur à l'École de Médecine et de Pharmacie d'Alger. Paris: J. B. Baillière et Fils. 1900.

The works on tropical diseases are beginning to multiply themselves, and none too rapidly in these days when physicians educated in northern countries are sent to the tropics, where the aspect of familiar diseases is often so changed as to render them almost unrecognizable, and where many unknown affections are encountered. The work before us is divided into seven parts: (1) vegetable parasitic diseases; (2) skin diseases due to the action of vegetable parasites; (3) animal parasitic diseases; (4) affections caused by noxious animals; (5) diseases due to physical and chemical agents; (6) auto-intoxication; (7) diseases of an indeterminate nature. The work is a valuable addition to the literature of tropical medicine.

La Chirurgia del Pericardio e del Cuore. Par Prof. Errico Giordano, Libero Docente di Medicina Operatoria nella R. Università di Napoli; Chirurgo Ordinario nell' Ospedale dei Pellegrini. Napoli: F. Sangiovanni. 1900.

This is an excellent little monograph on the surgery of the heart and pericardium. The work is divided into three parts, dealing respectively with the anatomy of the pericardium, the surgery of the pericardium, and the surgery of the heart. It is especially valuable on account of the very extensive bibliography which it contains. In reading the book one is placed in possession of all that is known and all that has been done in this interesting field.

Diet and Food, Considered in Relation to Strength and Power of Endurance, Training and Athletics. By Alexander Haig, M.A., M.D. Oxon., F.R.C.P., Physician to the Metropolitan Hospital and to the Royal Hospital for Children and Women. Second edition. Philadelphia: P Blakiston's Son & Co. 1900.

The views of the author of this little work in relation to uric acid as the cause of many of the common ills of mankind are too well known to need restatement here. In this book he goes a little further in placing fatigue among the conditions frequently caused by the presence of uric acid in the blood. The remedy, of course, is the same as that advocated by the author for other uric-acid manifestations, namely, a vegetable diet. The writings of Haig are always interesting because of his evident sincerity, but they are not necessarily convincing. Here especially ought the saying to apply, that the proof of the pudding is in the eating.

La Ginnastica Razionale senza Attrezzi. Par Dott. T. E. Gatti. Roma: L. Cecchini. 1899.

This little work treats of the various forms of exercise which are possible without the aid of apparatus of any sort. There are seventy-eight outline sketches showing the different exercises.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL—PATHOLOGICAL SOCIETY—BALNEOLOGICAL AND CLIMATOLOGICAL SOCIETY—SIR JOSEPH FAYRER—BIRMINGHAM UNIVERSITY AND THE CONSULTING AIDS CLUB—ROYAL COLLEGE OF SURGEONS—LONDON HOSPITAL—RECENT DEATHS—STORMS—SUNSTROKE—AMBULANCE SERVICE—MEDICO-CHIRURGICAL SOCIETY—PYORRHŒA ALVEOLARIS—LORD LISTER OPENS WESTMINSTER HOSPITAL LABORATORY—MR. MYLES, F.R.C.S.I.—SUICIDES—DEATHS OF DRS. ALTHAUS, WILLIAMSON, FITZPATRICK, AND BLAKE.

London, June 8, 1900.

There is little more to report from the prolonged sitting of the General Medical Council. The tenderness with which the corporations are treated is what one might expect from its constitution. The two colleges have formulated their objections to fall into line with the other bodies on the question of the first years of study. These two London colleges are determined if possible to maintain their right to recognize ordinary schools as places of scientific instruction, so that a few lessons in chemistry at a boarding-school are to enable the schoolboy to count himself a medical student. The Council wishes students to complete their general education and pass the preliminary examination before the five years' curriculum commences. The reasonableness of this requirement is obvious to every one except the rulers of the two colleges which dispute the authority of the Council to lay down a law to that effect, and the Council once more had not the courage of its convictions, and so it passed on to the lawyers the question of its power to enforce its regulations. If it had refused to register any student who had not complied with these regulations the recalcitrant colleges would have been on their knees; for of course the students would have resorted to other qualifying bodies, and these two would have lost more fees than they can hope to gain by thus stealing a march on the other corporations.

The Apothecaries' Society invited the Council to join in a lawsuit as to the right of a licentiate to call himself "physician and surgeon," but the Council decided to let the society pull its own chestnuts out of the fire.

There was much additional talk about personation, and as to this also refuge was sought in the legal advisers.

The difficulties of raising the standard of preliminary education were reported upon, and a fear was expressed of creating a dearth of candidates for admission into the profession—a notion which must cause curious emotions where overcrowding is most marked. The limit of age for entry was left at sixteen years, though a hope was expressed of raising it shortly to seventeen. The attention of these grave seniors might well be turned to the question as to whether boys of sixteen or seventeen are old enough to enter the wards of our hospitals.

The annual meeting of the Pathological Society was held on the 29th ult. The report indicated a prosperous condition with six hundred and eighty-one members. The laboratory meetings, a new departure on which I have commented, are pronounced a conspicuous success. Some alterations in the rules have been made to meet the developments of pathological science. A vote of thanks was passed to Mr. Gould, who acted for the president in the latter part of the session and to the other officials. Mr. Cheyne was appointed president for 1900–1901, and the other officers and council were also elected.

Among the exhibits was the thyroid of a puppy, from the mother of which the thyroid had been removed by Mr. Walter Edmunds. Nearly the whole thyroid was removed, leaving only one parathyroid and a morsel of thyroid proper. A few months later the bitch gave birth to the puppy, and it was found that the puppy's thyroid was large, the colloid being absent and the secreting cells lining the vesicles hypertrophied. These appearances were the same as Halsted had previously shown to take place in such circumstances.

It has been observed that women suffering from Graves' disease or from myxœdema improve in health during pregnancy. Perhaps the hypertrophied thyroid of the fœtus may compensate for the loss of the mother's thyroid.

The Balneological and Climatological Society has had the good fortune to secure an address by Sir Joseph Fayrer for its annual meeting, which was held on the 30th ult. Sir Joseph took for his subject "The Hill Stations of India as Health Resorts." He spoke of them not merely in reference to the treatment in disease and convalescence, but as places where Europeans might colonize. Not that he had proof to offer, but he thought there were some grounds for believing that there was a prospect of success in those stations, though none in the plains of India. There is every variety of climate in India, and some of these were described, to the delight of the society. Sir Joseph, however, only professed to touch the fringe of the subject, which he said might be investigated with advantage by the society.

Birmingham just now presents a curious contrast. Her new university is established, and Mr. Chamberlain has been made its first chancellor. The institution may be expected to infuse scholarship into the restless activities of the midland capital, and to encourage a high standard in the learned professions. Yet at the same time the chancellor's son, Mr. Arthur Chamberlain, is pushing in a most objectionable manner the consulting-institution which he has started in conjunction with the local Saturday fund on the lines of medical-aid associations and against the unanimous opinion of the local practitioners. Advertisements of this institution have appeared in the local papers (appropriately enough, in the columns devoted to quackery), which should bring it under the condemnation of the Medical Council, as would probably be the case had they been issued by a general practitioner. The patronage of the son of the Colonial Secretary ought not to protect it. The medical man who sells his services to it should be ignored by all other practitioners.

The coming election of the council of the College of Surgeons is exciting rather more attention than usual—perhaps because of the centenary to be celebrated. There are thirteen candidates for the four vacancies, but perhaps some of these will not go to the poll. The election will be on July 5th. The centenary is to be celebrated on July 25th, 26th, and 27th. On the first of these days there will be a conversazione; on the second a meeting in academic costumes, an address, conferring of honorary fellowships, and, of course, a dinner; on the third the Lord Mayor will give a conversazione. Objects of interest will be demonstrated each day in the museum, library, and laboratories.

At a meeting of the governors of the London Hospital the day before yesterday it was stated that the working-classes had diminished their contributions to the extent of £700 per annum since the managers had levied a charge of threepence for bandages, dressings, or medicines. This is what was expected by many when the new departure was determined upon, notwithstanding a general feeling that it was unadvisable, to use the mildest term.

The midwives bill is postponed to the 27th, and as that is an early day it may not then be taken up.

A select committee has been appointed on the rating of hospitals and other charities.

The medical, surgical, and hygienic exhibition opened on Tuesday and closes to-day. It is of the same kind as its three predecessors.

Mr. J. G. Mackinlay died on the 24th ult. He was oph-

thalmic surgeon to the Royal Eye and the Royal Free hospitals, and much esteemed. He was an original fellow of the Ophthalmological Society and contributed a number of papers to its Transactions. His health, never very good, had quite failed for the last year.

The war is taking a toll from the Royal Army Medical Corps as well as the other forces. Maj. T. A. Marsh and Capt. R. Fawssett have to be added to our list of heroes. South Africa has also called for civil surgeons, and death has taken some of these: Dr. Adair on board a transport, Dr. Irvine at Ladysmith may be named. The death of Colonel Hayes, R.A.M.C., is a fitting crown to his hard service and unflinching courage on the field. At Aldershot he had the care of returned invalids from South Africa, and, though suffering from malignant disease of the gullet, carried on his work until six days before he died.

London, June 15, 1900.

The week opened with promise of summer, but the heat increased so rapidly that it soon became oppressive, and then violent thunder-storms were reported from all parts of the country. The maximum shade readings of the thermometer exceeded the June average of the last thirty years by about 12° F. on Sunday; by 16° on Monday; and by 10 on Tuesday. Since then there has been a fall and showery weather.

There were military manœuvres on Monday, and our red-tape-ridden War Office provided no helmets, but sent the men out in forage caps; it is said the reason was that they had not enough helmets on hand. No one seems to have had the sense or the authority to postpone the manœuvres, and so the men were out all day exposed to the sun, with the natural result—six deaths and hundreds of admissions to hospital. At the inquest it further transpired that the men were without food all the time—eleven hours. It is said that the present forage cap is a design of Lord Wolseley's. Whether or no, it is useless as a protection from the sun.

The deficiency of London in ambulance service is attracting attention, and New York is being held up to us as an example. We are told you have a motor car fitted with every requisite for immediate aid and rapidly taking the sufferers from accident in the easiest way to hospitals or their homes. With daily street accidents London should be able to improve on her antiquated system, or rather want of system. An estimate of the number injured in our streets places it at fifty thousand yearly. Last week our hospitals received three hundred and forty-one cases. There is certainly scope enough for the best system. It seems, however, that the provision made is not regularly used—the police not seldom putting a person into a cab within a short distance of an ambulance station.

The Medico-Chi has adopted the alterations in by-laws recommended by the Council. The effect of these changes is that the publishing of the Proceedings will be discontinued, and the Transactions will contain reports of the discussions as well as the papers read at the meetings. Further, the fellows are no longer to be precluded from publishing their papers in the journals. After these changes were agreed to, the ordinary work was resumed by the reading of a paper by Mr. R. J. Godlee on "The Complications of Pyorrhœa Alveolaris—Riggs' Disease, as it is Sometimes Called." It consists of a spongy condition of the gums with recession, and deposit of tartar. This last is often regarded as the cause. Inflammation extends to the peridental membrane or periosteum of the fang, and suppurating pockets are formed. Not often considered serious, it may give rise to symptoms of grave disease, three examples of which Mr. Godlee related. The discussion was interesting as involving both medical and surgical points, but there was not much adjustment of view between the physicians and surgeons. The disease is so often looked upon as a dental affair that the remarks of Mr. Tomes were naturally listened to with attention. He pointed out that the majority of cases presented scarcely any symptoms, the discharge being so commouly swallowed; but at night a bloody fluid might run out and stain the pillow, thus leading to its detection If without obvious cause pressure along the margin of the gums caused purulent fluid to exude, the diagnosis was clear. Antiseptics should be applied, but the improvement they produced did not always last. Riggs' method of scraping the margin of the alveolus was tedious and painful, and with this plan relapses also occurred. If a tooth was extracted from an affected socket the wound seldom went wrong, though that might seem strange. The question as to the local or constitutional origin of the disease was raised, and something was said on each side. It occurs in animals, is common in glycosuria, is often symmetrical, and sometimes seems to be hereditary. Gout and rheumatism were mentioned as often associated, and one speaker thought many cases of malignant endocarditis might originate in the disease.

Lord Lister opened the new clinical laboratory of the Westminster Hospital on Tuesday. It has cost some £2,000. His lordship said the public owed the managers a debt of gratitude for so wisely spending the money, and urged that before many years it would be generally recognized that such laboratories were among the most important means of rendering good service to mankind.

The presidents of the two royal colleges also spoke.

Mr. Myles has been elected, unopposed, president of the Royal College of Surgeons in Ireland. At an earlier stage there was a threat of opposition founded on an unaccountable blunder. A circular was issued charging Mr. Myles with associating himself with the Irish League. On being called to account by a writ for damages, his opponent had to acknowledge he had in some way confused two paragraphs in an evening paper, and so he tendered an ample apology and had to pay costs. Hitherto I am told politics have not been introduced into the college elections, and when feeling runs so high it is to be hoped the old reticence will continue to be observed.

There has been quite an epidemic of suicide lately—nearly sixty cases have been reported within a month, a number far beyond any recorded in any month for the last ten years. One poor lady took morphine and then shot herself for fear of being buried alive. A medical man took prussic acid, but the jury at the inquest could not say whether by mistake or intentionally.

Dr. Julius Althaus, well known as a writer on neurology and on electrotherapeutics, died on the 11th inst., aged sixty-seven years. He was one of the founders of the Hospital for Epilepsy and Paralysis, where he worked for some twenty-eight years. On his holiday last year he injured his knee, and his friends noticed that from that time he had failed. In fact, he had attacks which were spoken of as gout, but some thought the explanation insufficient. He has been quite laid aside for some months, and though the case was a little obscure, it seemed to be phlebitis, and so it has proved.

George Edward Williamson, F.R.C.S., died on the 5th inst., within a week of a full day's work at the Royal Infirmary, Newcastle-on-Tyne, to which he was ophthalmic surgeon. He had also been professor of physiology and surgery in the Durham College. He was only forty-eight years old.

Dr. Thomas Fitzpatrick, who died on the 31st ult., was a man of many attainments, a distinguished graduate of both Dublin and Cambridge universities, 1862-67. You may have met with his "Autumn Cruise in the Ægean" or his "Transatlantic Holiday." Among his accomplishments may be mentioned acquaintance with several languages, including modern Greek, and a wide knowledge of ancient classical literature.

Dr. J. Gibbs Blake, of Birmingham, died on the 27th ult. He was one of the original trustees of Mason College and bestowed great labor on its foundation. He was educated at University College, where he had a very distinguished career, crowned by the London M.D. and his election to a life governorship. He was also an accomplished classical scholar and had great artistic talent.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE POZZI-DEVILLERS DUEL—DEATH OF DR. CHÉRON—NETTER'S ARTICLE ON PLAGUE AND MEASURES TAKEN AGAINST THIS DISEASE—PROFESSIONAL SECRECY IN FRANCE—OFFICIAL LIST OF FESTIVITIES CONNECTED WITH THE THIRTEENTH INTERNATIONAL CONGRESS.

Paris, June 15, 1900.

A general topic of conversation in the social as well as the medical world in Paris is the Pozzi-Devillers duel, which took place last Sunday, on June 10th. This duel, like so many others of recent occurrence, has sprung out of the political agitation brought on by the Déroulède trial before the senate. Dr. Pozzi, the gynæcologist who performed an abdominal operation on Sarah Bernhardt, has been a senator for several years, like Dr. Labbé, the great surgeon, who performed gastrostomy in 1876 to remove a fork from the stomach of a waiter. He was therefore obliged to take part in the discussions which were held at the Luxembourg during the progress of the trial, and it would seem to be clear that he was in favor of banishment being pronounced against Déroulède. Dr. Devillers, Déroulède's physician, was present at the last meeting held in the rooms of the Medical Club in the Avenue de l'Opéra on June 7th. This club was founded a few months ago by Dr. Doléris, and Dr. Pozzi had been offered the president's chair. Dr. Devillers began by making some disagreeable remarks to Dr. Pozzi about politics, but but the latter told him he did not consider a medical club a fit place for discussing such a question. Dr. Devillers thereupon insulted him and

threw his glove in his face. The man was at this junction taken care of by his friends and led into another room. On hearing Dr. Pozzi say that he thought it likely that Devillers was not in his right mind, he burst forth again into the most violent language. As might be expected, a duel was decided upon, and though it is thought advisable generally to carry out these encounters within twenty-four hours after the offence, the "rencontre," as they say in French, only took place on Sunday, and was carried out in the most orthodox manner. The place chosen was Louveciennes, a small town near St. Germain-en-Laye, and though Dr. Pozzi had not done any fencing for the last ten years, he chose swords. Dr. Devillers is, on the other hand, an expert fencer. The swords were sterilized to prevent any infection of the wounds, and immediately after the word was given Dr. Devillers ran his sword into Dr. Pozzi's right hand between the fourth and fifth fingers. Dr. Pozzi was therefore unable to continue, and the two adversaries shook hands. I have been told that Dr. Devillers wished to wound Dr. Pozzi seriously, a fact which does not agree with the result of the duel. It seems that Dr. Devillers will be prosecuted for having attacked a magistrate in the exercise of his functions, Dr. Pozzi having this quality while acting as senator in the recent trial. A procedure, as it is called, has already been put in motion against him, but Dr. Pozzi, who has shown throughout a most conciliatory spirit, states he will do his utmost to prevent any further action being taken in the matter.

It can be asked if it is advisable for doctors to take an active part in politics, when they have a large practice to attend to. Dr. Pozzi's political opinions are not of a nature to attract to him the sympathy of the Faubourg St. Germain, as the French nobility residing in Paris is called, as it seems that he advocates measures which are not conservative. However, medical men are being heard of more and more in political life, and can bring quite a good deal of influence to bear upon the measures and laws enacted at the Chamber of Deputies.

Dr. Jules Chéron, who was well known for his works on subcutaneous injections, died recently in Paris. He was the son of a military doctor, and began by taking up the study of natural history. He decided later to become a physician, and was chosen as doctor of the St. Lazare Infirmary for Prostitutes in 1870. His principal works are as follows: "The Use of Electricity in the Treatment of Fibromas," "On Treatment by Oxygen in Consumption," "The Cicatricial Properties of Picric Acid." He was one of the first to use artificial serum, and he recommended the use of a solution containing carbolic acid as a hypodermic injection in the treatment of certain forms of general debility and exhaustion. His formula was: Pure carbolic acid, 1 gm.; chloride of sodium, 2 gm.; sulphate of sodium, 8 gm.; phosphate of sodium, 4 gm.; boiled distilled water, 1,000 gm. From 5 to 120 gm. was to be injected into the gluteal or retro-trochanteric region very slowly; slight massage was performed, and the injection was repeated according to the needs of the case. For the space of nineteen years Dr. Chéron directed the *Revue Médico-chirurgicale des Maladies des Femmes*, in which paper he advocated conservative treatment, being bitterly opposed to the surgical interventions which were too much in fashion a few years ago.

Dr. Netter, who is an authority in France on questions of hygiene, has published recently in the *Presse Médicale* an article on the spread of plague in Australia and America. A map is given, wherein are indicated the different ports visited by the scourge. This article and that of Dr. Lochelongue, about which I have already spoken, show that we are awakening to the fact that stringent measures should be taken to prevent the spread of this disease. A method for suppressing rats is now being studied in Paris, and measures have been taken by the mayor at Marseilles to insure the destruction of all rodents such as mice and rats. He published a decree offering a premium of half a cent for every mouse and of a cent for every rat, dead or alive, that should be delivered at the municipal offices in the city. In the space of two weeks after the promulgation of this order, five hundred and two rats and one hundred and eighty-four mice had been handed in.

Professional secrecy is a rule which is enforced with a great deal of strictness in France, and a recent occurrence will show how far this principle will command silence on the part of a medical witness. For a case of supposed suppression of childbirth tried before a French court, one of the witnesses was the midwife who had attended the woman accused of the deed. When judgment was pronounced, it was clearly stated that the testimony of the midwife would not be accepted, and, on the attorney-general sending the case before the criminal chamber of the court of cassation, the action was decided against him. In the decree published by this august body it was declared that all medical attendants were bound over to complete professional secrecy, barring those cases in which the law demanded divulgation. As such cases no longer exist, it may be said that professional secrecy is now of an absolute nature in France.

The official list of the festivities that are to take place in Paris in connection with the Thirteenth International Medical Congress has at last been published. On August 2d there will be a reception offered by the president of the council of ministers in the name of the French Republic. This reception will most likely be held in the rooms of the Palais Bourbon. On August 3d there will be a festival given by Professor Lannelongue. Special invitations will be sent out for this social function, which will take place either in Dr. Lannelongue's large house in the Rue François I. or else in some hall chosen for this affair. On August 5th the president of the republic will receive the members of the congress at the Elysée in the evening. On the 8th there is to be a grand festival in the palace and gardens of the Luxembourg, under the direction of the bureau of the organizing committee. The municipal council may also have some sort of entertainment, and of course in each section there will be special dinners and receptions. I may state also that at all these functions the wives, sisters, and daughters of the members of the congress will be invited, and a special ladies' committee will be established to receive them.

LETTER FROM BEYROUT, SYRIA.

(From our Special Correspondent.)

The spring is bringing on the time of flowers, some one said or sung some time ago. It came to us with the 20th of March or thereabouts. Flowers are everywhere; on the highways and hedges, even on the trees—primulas and primroses with their companions, the fair chaste marguerites, the little speedwell "with its darling blue"; roses of all tints, most beautiful and most fragrant; camellias of surpassing beauty, and perfect poppies, the largest and comeliest we have ever seen, and many more besides. So much for the flowers.

Disease is not rife among us at this time. There is talk of plague coming on; but we think it is a myth. Nevertheless, it has been reported at Cairo and at Smyrna, and it is thought to be approaching us. If it does, it will do its duty on the rats that stroll about our streets, where the barley is on sale, regardless, may it be understood, of passers-by—the rats, we mean.

An order went forth the other day to kill six hundred dogs. This was on account of a young man of the town having been bitten by a little dog that he owned. The master of the dog (which saw instant death) was treated by modern methods, and has now no fear of the infection. Speaking of the spring, I forgot to say that the swallows have come. They are killing millions of mosquitos a day. Here, no one would think of pointing a gun at one of those swift scavengers of ours. What our death rate is here (as, I think, I said before) I cannot tell, as I have got no references; but in any case our little feathered friends can reduce it.

Lebanon has got his night-cap on and looks well. It is cold up there. Here we have an average of 73° F. in the shade. Out in the sunlight it ranges about 110° F., and the glare is far beyond the electric light. The changes of temperature in this month of May are very great just now—rising and dropping 10° F., coming and going, and making us all miserable from a disease which, rudely speaking, has been facetiously baptized as "sniffles." It is not aristocratic enough to be the great influenza, but it seems to have an affection for it (perhaps an offspring). It does not do so much evil, however, as the after results are more or less *nil*. The misery during the attack, which lasts for about a week, is modified by the patient's wishing for a better land. The treatment, of course, depends on the circumstances and the patient's history—the attendant physician's judgment to boot. Dysentery and enteric seem to have been doing their duty in the beleaguered towns in far South Africa. Horse broth and mule stew with fricasseed locusts might have been good enough without risk; but "pea-soup water tinted drab," wherein dead horses were having their last siesta, was not good for what is generally spoken of as "health"; and many went down under the regimen.

We have had a wind on us for the last three weeks. Rain came with the advance of spring, and was of a sporadic character, raining, as it did, spasmodically and most uncertainly, and even when the sky was blue. It cooled us and refreshed us, and laid the dust, and we were all glad for those pigmy showers.

A catastrophe occurred on April 21st on one of his Majesty the Sultan's torpedo-boats. The boiler exploded, and out of seventy there were seventeen persons either rescued or saved. One man was carried home, dying two hours afterward, presumably from shock. Rigor mortis setting in four hours later, a movement of the hand was seen. A

consultation was called, and he was pronounced dead, as he most certainly had been for six hours at least.

Mosquitos and cock-crowing are here, both of which are mischievous, and, other reasons apart, indirectly insalubrious, as they prevent sleep. The mosquito does his duty as a manufacturer of germs—besides, the source of the—be it confessed—necessity of looking up our vocabulary for fresh words. This causes much evil to body and spirit.

In conclusion we may say that the authorities are regularly watering our streets lately; there is very little dust—formerly a notable thing here—and we think the people of this land can (even by frightening them) learn to be cleanly.

By the way, I have just noticed an article in *Treatment* suggesting changing of camps in cases of enteric or diarrhœa or dysentery or any of the other diseases that come to the beleaguered and to those who have to sit and watch them. We will remember the advice of an old expert in fevers, and those of that ilk—"Always change your patient from room to room, morning and evening, and keep your windows open." He was very successful in his treatment, and others who may adopt his method may be so, too. When we are shut up we have no option, but being free, it devolves upon us to keep ourselves and others clean and pure as much as in us lies.

LETTER FROM BRAZIL.

(From our Special Correspondent.)

THE PLAGUE AT RIO—GENERALIZATION OF YELLOW FEVER.

São João del Rei, Brazil, May 25, 1900.

Although the bubonic plague has been threatening Rio de Janeiro for the past six months, there being one or two sporadic cases on two different occasions, it is only within the past week that it can be said to have gotten a foothold. On the 16th inst. there were two cases reported as suspicious. Both patients died, and the bacteriological examination proved them to be genuine cases. Upon examination it was discovered that within a short time seven others had died in the same locality presenting similar symptoms. Since that date a large number have been isolated, and on the 24th one case was found in another part of the city several miles from the primary focus. On the 18th inst., at the laboratory in connection with the custom house, and in streets adjoining, there were found a number of dead rats, and the director of the laboratory discovered the plague bacillus in the one he examined.

The section of the city in which the first cases were found bears the pleasing name of Saude (health); however, the following extract from one of the Rio papers would indicate that there is considerable irony in the name as applied to that locality:

"The police inspector of the fifth city district made a visit of inspection last night, and at No. 7 of the Alley Costa Velho found a tavern in which were sleeping twenty-four persons, among whom were the well-known thieves Perua, Fina, and Alsaiate, who were removed to jail. In No. 55 Misericordia Street they found eighty-six. In No. 94 of the same street were found seventy-seven in a deplorable state of uncleanness. In No. 44 were found one hundred and two; and in No. 19 of the same street were sleeping sixty-six. In this house the air was unbreathable, in all parts there being a most nauseating smell. Immediately upon learning of the vile condition of these lodging-houses, Dr. Graca Conto took energetic measures to improve them."

Another extract from the same journal, May 25th, gives some idea of the origin and present extent of the disease:

"It has been absolutely impossible for the sanitary authorities to circumscribe the plague which is attempting to fix itself in this city. The cases have appeared simultaneously in various points, and from this come the difficulties the authorities have in trying to limit the evil to a single zone. The absolute lack of cleanness in which are found the sections of Saude, São José, and others has helped wonderfully in spreading this terrible evil. The hundreds of third-class passengers who have come to this port in various steamers from Europe and the Argentine, with large quantities of dirty baggage, have also been a powerful agent in making our sanitary condition worse. The sanitary authorities are sparing no pains or expense in fighting the evil, and consequently our people ought to be confident and, above all, heed the hygienic counsels. If they will do this they will render inestimable help to the authorities."

Dr. Nuno de Andrede, chief federal health officer, is in charge and is employing the same means which he used in Santos and São Paulo, where it was conquered in a short time. A quarantine station has been established at Ilha Grande, about six hours from Rio, where all vessels must be disinfected. Disinfecting-stations have been also established at the terminal railroad stations, where all passengers and baggage must be disinfected. There seems to be no panic, and the presence of the disease has not affected the money market, which here is a very good thermometer of public confidence. There is not much fear that it will spread into the interior, and it is sincerely to be hoped that it will be stamped out in Rio itself.

There has been very little yellow fever in Rio this season, but epidemics of it have recurred in several interior towns where it was never known before, and there is a fear that it will eventually reach all parts of the country. Juiz de Fora, in the state of Minas, which was so terribly visited last year, is again suffering from the same evil, although the city spent a large sum in perfecting its sewerage system during the past year.

THE MEDICAL ASPECTS OF THE SOUTH AFRICAN WAR.

(From our Special Correspondent.)

This will be the last regular communication that I shall send your readers, for although the war still flickers on, the medical aspects are not likely to present any more novel features. Since my last communication the British flag has been hoisted in Johannesburg at the end of May and five days later at Pretoria by Roberts; while Buller has forced Almond's Nek, with the result that all the Boers have been driven from Natal and that the operations are now being conducted entirely upon the soil of the republics. Two minor Boer victories after the occupation of Pretoria by the British have shown that the Boers are able to act with concerted force and great spirit, but although guerilla resistance is still to be expected, regular pitched battles are not now likely to occur. Hence it may be taken for granted that the medical lessons to be learned from the campaign are at an end, although desultory fighting will go on for some time, while the ravages of epidemic disease will certainly add many hundreds to the total losses of either side.

The Total Losses of the British up to the occupation of Pretoria amount to 25,000 men, the figures being made up as follows:

	Officers.	Men.
Killed in action	235	2,283
Died of wounds	63	551
Missing and prisoners (excluding those who have been recovered)	186	4,486
Died of disease	112	3,609
Accidental deaths	...	58
Sent home as invalids	664	13,481
Totals	1,260	24,468

Total losses (exclusive of sick and wounded men now in British hospitals in South Africa), 25,728.

The figures are instructive. In eight months the British army has lost twelve and one-half per cent. of its strength. The officers, whose ratio to the men is less than 1 to 100, have lost in the proportion of 1 to 10 killed in action and 1 to 9 died of wounds, the figures showing that the officers have not feared to take risks and have had no advantages whatever over their men in the way of surgical treatment. In death from disease the ratio of officers to men is 1 to 30, and here the superior accommodation in officers' quarters and the superior food at their messes have probably not counted for so much as the possession of private means. On the march the officers and men have fared alike, but in times of inaction the officers have had a healthier or less crowded environment and have been able to purchase small comforts. The two largest items in the roll call of disaster, being between them responsible for more than two-thirds of the total, are the lists of missing and prisoners and of invalids sent back home. These men, or at any rate a large proportion of them, can be regarded as only temporarily lost to their country, for the long sea voyage to England as a rule completely recuperates the sick, while the prisoners who are daily being released by their friends, despite stories of their treatment, have been found generally in good condition.

The Prevalence of Enteric Fever and Dysentery among the British troops was by the end of May simply awful. The figures with regard to the former, when they can be made known, will constitute a record. They are being very carefully kept, as they should prove an absolute answer to the question that all medical men, military and civil alike, are putting as to the efficacy of the anti-typhoid serum in-

oculation. At every hospital that I have mentioned patients are being nursed for enteric fever, and several, the Portland and the Langman, for example, have been compelled to increase their accommodations, which in the time of hot fighting had been found sufficient. The percentage of recoveries is very large, and, as I have just pointed out, once the patient is sufficiently convalescent to be put on board ship, he usually arrives in England well, the voyage home being exactly what he requires to build him up again.

In Conclusion, I trust that your readers will have been able to derive the proper medical lessons of the war from the brief accounts that I have sent. It may have seemed that I have occasionally dwelt with unnecessary detail upon the merely military conduct of the campaign, but unless the progress of the different generals was followed the enormous difficulties of transport and the reasons for the locations of the hospitals would not have been apparent. I need not recapitulate the views that must, until some new weapon of precision alters both prognosis and treatment, prevail among all surgical authorities concerning bullet wounds. Sir William MacCormac and Mr. Treves have laid down rules which will be authoritative until new conditions upset them. But it will not be out of place to enumerate briefly the reasons why the British Royal Army Medical Corps has emerged from the fierce trial of the South African war with so much credit to themselves. Firstly, their organization was excellent, the military training at Netley, following upon the course of hospital work necessitated to qualify for the corps, making of them a body of obedient, hard-working men. Secondly, their undermanned ranks were early filled by well-chosen young men of hospital experience, able adjuvants in the wards and still fresh from the discipline of their civilian staff surgeon. Thirdly, the corps was cheered as well as helped by the presence of great scientific surgeons, so that they always felt that undeniable testimony would be forthcoming to the value of any good work, and that a first-class surgical opinion could always be obtained for the asking in cases of difficulty. Fourthly, the choosing of the hospital sites was left to the medical department, so that the sick when brought to the base were always treated under the most favorable hygienic conditions. Bearing these facts in mind, I believe that the result of the war will be a reorganization of the Royal Army Medical Corps, so that the success which they have secured in this campaign by extraordinary efforts will in future campaigns follow upon ordinary routine. And the other first-class powers of the world, who are compelled to keep a standing army, will probably organize the medical department of their armies in much the same direction. The pay of the Royal Army Medical Corps will be raised, chiefly by way of special allowances, so that the service may be made attractive to the best class of young medical men. Leave will be granted to the medical department in order to enable them to return home occasionally and revise their learning; and other encouragement will be offered to them to pursue original scientific study. And a reserve of first-class operating-surgeons will in some way be affiliated to the corps, so that the government, by paying a small annual sum in times of peace, will be able to secure the pick of surgical skill in times of war. It should, and possibly will, also become the rule of the British War Office to send a medical attaché to join the head staff of the army of any other nation engaged in war, a practice which has been observed by the German War Office in South Africa.

THE PLAGUE IN RIO DE JANEIRO.

To the Editor of the Medical Record.

Sir. A note on the recent outbreak of bubonic plague in this city may be of some interest, although full information at this time is hard to obtain.

After a long delay, probably due to a reluctance to allow quarantine to mar the celebration of the fourth centennial of the discovery of Brazil, the government, on May 21, 1900, officially declared the existence of bubonic plague in the city of Río de Janeiro. Sporadic cases of plague have been observed here since January last, and several cases of adenitis inguinalis perniciosa have proved fatal, as may be seen in the reports of the United States Marine-Hospital service. The manner in which the original case was introduced is still a disputed point, but the best-informed here believe that it was brought on a ship arriving here from Tamatave, Madagascar. On May 15th a suspicious mortality among the rats in the custom house was observed, and upon examination of the bodies, the bacilli of pestis bubonica were found, and cultures were made in the bacteriological laboratory under the direction of Professor Lerin and Dr. Gomes. The authorities were informed, but no official action was taken. About the same time several cases of plague occurred from which the typical bacillus was obtained. When quarantine was finally declared, there were nine cases and five deaths reported. Since then the daily increase has been as follows:

Date.	New Cases.	Total Cases.	Deaths.
May 23d	3	12	5
May 24th	5	17	2
May 25th	4	21	
May 26th	3	24	2
May 27th	9	33	7
May 28th	6	39	2

Through the courtesy of Dr. Havelburg, of the United States Marine-Hospital service, to whom I am indebted for much of my information, I am able to state the above figures with some certainty.

Prophylactic measures have not been taken with much apparent energy, although the usual general quarantine has been established. Vessels leaving for Brazilian ports must be disinfected at Ilha Grande (the regular quarantine station), and no vessels are allowed alongside the wharves to load or discharge cargo. Local measures consist of isolation of the patient by removal to the Jurujuba Hospital, across the harbor, and by disinfection of the house with sulphur or formaldehyde. Incidentally the people object strenuously to sanitary restrictions and place every obstacle in the way of disinfection and cleanliness. The following quotation from the Rio *News* of May 22d gives an idea of the feeling toward modern medicine down here. After noting the fact that the presence of the plague has been officially acknowledged and the city placed under sanitary law, the editor says: "With all due respect to the professional gentlemen who have discovered the bubonic bacillus in the blood of a guinea-pig after being inoculated with the blood of a person dying of suspected plague, we are compelled to say that we do not believe there is any such thing as bubonic pest in this city, nor that there is any occasion whatever for the irritating and prejudicial restrictions placed upon the commerce of this port. The doctors are clearly bacillus-mad, and the losses caused by their ridiculous restrictions are worse even than any likely to be caused by the plague. These quarantines are as worthless, besides, as they are prejudicial, and, to speak plainly, they serve no other purpose than to afford extra pay to a few doctors and quarantine employees."

Professor Lerin and Dr. Gomes have been studying the plague in the bacteriological laboratory, and Professor Lerin has succeeded in obtaining a prophylactic similar to that of Haffkine. Until last week only a few experimental inoculations had been made, but now many people are being inoculated, and figures should soon be forthcoming.

As to the treatment of the disease in the hospital, little can be learned. A shrug of the shoulders may be expressive, but it is neither encouraging nor enlightening. The Yersin serum can be obtained here, but, I believe, has not been used.

The outlook is certainly not promising. The poorer classes are half-starved, half-naked, and altogether dirty. They live in dirty districts which the authorities do not seem disposed to clean. There is every opportunity for a large mortality in the next few weeks, unless vigorous measures are undertaken at once.

James R. Whiting, Jr., M.D.

Rio de Janeiro, Brazil, May 29, 1900.

THE SAVING OF LIFE IN CUBA.

To the Editor of the Medical Record.

Sir: I have read your remarks on the report of Chief Surgeon Ives of the Department of Matanzas and Santa Clara. I had just received an extract from the report of Maj. George S. Cartwright, quartermaster, who has had charge of the Department of Street Cleaning and other sanitary improvements, such as drainage, etc., and I send you the number of deaths per month in Matanzas. As an object-lesson I think it will emphasize your remarks:

	Deaths.		Deaths.
December, 1898	449	September, 1899	102
January, 1899	323	October, 1899	72
February, 1899	257	November, 1899	88
March, 1899	205	December, 1899	95
April, 1899	136	January, 1900	89
May, 1899	131	February, 1900	85
June, 1899	118	March, 1900	107
July, 1899	121	April, 1900	68
August, 1899	112		

The city of Matanzas had a population of 38,000 in 1898. It would appear that American occupation has not been a failure so far as saving life is concerned.

S. S. Cartwright, M.D.

Roxbury, N. Y.

Society Reports.

PRESENTATION OF A LOVING-CUP AND ALBUM TO PROF. ABRAHAM JACOBI, M.D.

At the annual meeting of the Section on Diseases of Children of the American Medical Association, held at Atlantic City, June 5, 1900, a very unusual and interesting ceremony took place, occasioned by a dinner to Dr. Abraham Jacobi and the presentation of a loving-cup to that gentleman.

Dr. Louis Fischer, of New York, secretary of the Section on Diseases of Children, American Medical Association, made the presentation of the cup as follows:

Mr. Chairman, Friends, and Members of the Section on Diseases of Children: It appears to me that it is with malice prepense that I have been chosen to address our honored guest of the evening, Dr. Abraham Jacobi. The committee in charge have evidently noticed that a handsome woman chooses as her steady companion one who is extremely plain and homely; her reason for such action is evidently a desire to shine by contrast. In this way I explain perfectly the fact that upon me has devolved this pleasant task. My youth and verdancy, I suppose, are to set off our guest's venerable age; inexperience is to be placed in juxtaposition with the accumulated lore of three generations; the bubbling, fervid passion for his chosen profession of the Bachelor of Medicine is opposed to the staid, dignified, and ripened love of the Master, the Father, the Nestor of American pediatrics.

But, be that as it may, I take courage in knowing that I stand here as the representative of American pediatrists, as the mouthpiece of the followers of the Doctor Jacobi, and as an admirer among admirers of the many lovable qualities and the sterling character of the man Jacobi.

It is unnecessary for me to discourse on the achievements of our Grand Old Man! His numerous contributions to medical science are well known to you. From 1859, when he published with Noeggerath "Contributions to Midwifery and Diseases of Children," to the present year, 1900, when at Paris, as an honorary president at the International Congress, he delivers an address on "Report on Artificial Feeding and Sterilization of Milk"—during all these years we find him never tiring, ever busy, ever discovering, ever studying, and ever teaching. His reputation, indeed, is far from being merely local, or confined only to the limits of this section, proud to call him founder. We find him known, quoted, honored, loved abroad as well as at home. As an example of the regard in which he is held, allow me to mention that such societies as the Deutsche Gesellschaft für Kinderkrankheiten sends congratulations signed by their prominent members, on the occasion which we are gathered to celebrate to-night.

But enough of this! I fear that by enumerating all the virtues of our guest, I should most assuredly bring down upon my head the imprecations prompted by his modesty. I had occasion to ask him in a joking way, whether all these celebrations might not prove too much even for his modesty, and whether they would not—to use the vernacular—swell even his cranium. He laughingly answered that such could not be the case, since he believed only about one-half of all the encomiums showered upon him. You must, therefore, not blame me if, to punish him for his disbelief in honestly expressed opinions, I omit three-quarters of what I intended to say, or rather of what you intended to say through me. But I shall use his own words and apply them to him with perfect propriety. In a presentation speech delivered nineteen years ago in honor of the noted Dr. George F. Shrady, Dr. Jacobi spoke as follows:

"We know quite well that he meant to perform his duty only. Neither he nor any other sterling man works for thanks or appreciation expressed in any way. The best intellectual and social labors are always performed by those who work from inner necessity only. But when one man works industriously, honestly, and usefully in the service of society, country, or scientific body, it is both natural and becoming, it is good instinct and wise principle on the part of those who derived benefit from his personal efforts to prove themselves worthy of them by word and action."

And this, my dear friend Dr. Jacobi, we tried to do to-night. I beg you to accept this loving-cup as a token of our appreciation of your successful efforts in the behalf of science and in our behalf. May you remain with us a long time to come; yes, may you live to witness the presentation of loving-cups on the seventieth birthdays of those who now take such delight in offering this one to you.

And lastly, as regards these engrossed, signed resolutions, we beg you to look upon them as an expression of our desire to be remembered by you as your friends and admirers.

Permit me to read them:

"*Whereas*, In the fulness of time, the life and career of men conspicuous for unselfish devotion to duty become the common property of all; and the subject of pride to those with whom he may be connected by reason of friendship, respect, and love, whose work has impressed not only those with whom he is surrounded, the student to whom he spoke, the brother with whom he advised, the profession with whom he dwelt, but the whole world of medicine, and most especially that pertaining to the diseases of children, alone in the ripeness of his years, with a reputation unsullied, and the pride of his profession, stands Abraham Jacobi, 'The Father of American Pediatrics,'

"We, his friends and admirers, brethren in the same profession, and followers to his teachings, bring to him our felicitation. We entertain for him that respect and esteem which has been engendered by his many estimable qualities. That unusual progress that has been made in advancement of the scholastic reputation of the institutions, societies, or associations with which he has ever been connected.

"As an expression of our deep and enduring appreciation of his unvarying courtesy toward all; his unflagging interest in the professional welfare of all; and his indefatigable efforts for the practicable and liberal enlightenment in the subject of pediatrics—

"We, the members of the American Medical Association, and especially the Section on Diseases of Children, of which he was the original founder, tender to Abraham Jacobi every sentiment of veneration and respect and gratitude for that unvarying virtue that points to him as the true physician, and as a partial acknowledgment of the great obligation to his zealous personality present him with this loving-cup, and hope that the memories of our yearly intercourse may ever linger with him."

Toasts were given and responded to as follows: "The American Pediatrist," by William Perry Northrup, of New York; "The International Medical Congress," by F. X. Dercum, of Philadelphia, Pa.; "The American Medical Association," by Joseph M. Mathews, of Louisville, Ky.; "The Section," by A. C. Cotton, of Chicago, Ill.; "The Medical College," by James C. Wilson, of Philadelphia, Pa.; "The Deceased Members," by H. E. Tuley, of Louisville, Ky.; "Fraternal Greetings," by John H. Musser, of

Philadelphia, Pa., William Osler, of Baltimore, Md., Henry Koplik, of New York, N. Y., and R. C. Moore, of Ohama, Neb.

Dr. Jacobi replied as follows:

Mr. Chairman, Ladies, and Gentlemen: When I was invited to be present at your annual dinner, I took it for granted, until this afternoon, this was to be an informal affair, and no address was expected of me. The outcome is quite fortunate for all of you, for I shall be brief, but less so for me who hates to be unjust to men and things. Knowing I should find many friends here, I accepted the invitation, though I admit that my eagerness was mingled with sadness. The latter is based on the fact that for eighteen long years—though engaged in the same work with you and every honest professional man—I have not been inside your doors. After all, however, I know I belong here, for I am among pupils, co-operators, peers, or masters as the case may be, but always among friends.

I am afraid when I speak at all—I always was a better listener than talker—I shall repeat what I have said a great many times before. It is true a man may quote himself, and copy his former sayings without quotation marks. In that respect I have the advantage over all of you. They have told me so often lately I was seventy years old, that I begin to believe it myself. Now, in scores of years I have said many things that fortunately are forgotten, and when I repeat them now and then for a new generation, they are not remembered. Indeed, perhaps your fathers were my pupils. Think of it! it is nearly a generation that Busey and Rotch and I founded this section, which has since gone on flourishing and growing.

It was a wondrous contrast to former failures. Twenty years previous to that memorable meeting at Richmond, I undertook to found a section for pediatrics in the New York Academy of Medicine, and failed utterly. Evidently neither I nor the time was matured. It is true that a few papers and books had been written on the, or on some of the diseases of children, but they were isolated creations. You are well acquainted with the names of Dewees, Eberle, Condie, Ch. D. and Forsyth Meigs, W. V. Keating, and their individual exertions. It was only in 1860 that the first systematic instruction could be arranged for the New York Medical College, for the University Medical College in 1865, for the College of Physicians and Surgeons in 1870. In that same decade other schools in the Atlantic States followed those examples. Among the men who were at that early time most active in the study of diseases of children, I consider as most prominent J. L. Smith, of New York, and Parry, of Philadelphia. I should also mention my friend Fountain, of Davenport, Iowa, whose tragic end some of you may have found described in my treatise on diphtheria (1880), or in the famous patriarch Stillé's "Materia Medica and Therapeutics." Fountain's history is brief. Both of us experimented with potassic chlorate. A letter I wrote him on the results of my experiments with one-half ounce of the drug, consisting in temporary polyuria, crossed the news of his death, which was caused by his taking one ounce with speedy fatal termination. He was an unselfish and enthusiastic worker, and neither his life nor his death should be forgotten. If he had been a general, he would be remembered by a monument. Being only one of us, maybe nobody knows now where it is that the soil covers his remains. That was forty years ago. Sketches of the history of pediatrics in the United States have been published by S. S. Adams and Crozer Griffith; with both of them you are acquainted. Its progress is marked by the interest taken in it by a large number of industrious and scientific men, and by the co-operation of many of them for a common end. Such co-operative enterprises are John M. Keating's "Cyclopædia" and L. Starr's "American Text-book," accompanied or followed by two journals exclusively dedicated to pædology.

All this you know as well as I. With some of the phases of this development many of you, who have worked so assiduously, are better acquainted than I. What is particularly encouraging in the rapid strides pediatrics has taken, is not only the charm its study has by itself, but the mutual relation of pediatrics with all branches of medicine and its special doctrines; so that it gives and takes in equal measures. A narrow specialism has never been exhibited in pediatrics or in pediatrists. Co-operation, as it is the signature of the end of the century in commercial enterprises, is also the source of unprecedented results in medicine; it is true, on a different basis and with different results. Combination of efforts in financial and commercial enterprises is apt to lead to jealousy and avarice, and to prove destructive to the public welfare; in scientific pursuits it improves and benefits all. This sort of scientific, moral, and professional "trust," as they call it, is beneficial to mankind.

With the development of pediatrics in our and in other countries, my name has often been connected; also by you, to an exorbitant degree I am certain. It is true I commenced at an early time to furnish abstracts of European literature; soon I ventured into writing papers. In that early time I published a case of intussusception with obstructive hæmatomata, or perhaps obstructive hæmatomata with intussusception, also an essay on the diagnosis and pathological importance of the premature closure of the fontanelle. That was—if you permit me to speak of antediluvian times—in 1858. In the next year Noeggerath and I published a big volume of contributions to midwifery and the diseases of women and children, of which I speak because Osler could not find it, and, therefore, according to the pathologic and dead-house turn of his mind, which probably never admits anything he has not seen or felt, thought it was perhaps apocryphal. I say there is, or rather was, such a book, and it was one of my great successes, financial and otherwise. The book appeared, was sent to the journals, was favorably criticised, and made some reputation for the authors; but nobody purchased it. We paid $1,000 for printing and publishing. After a few years we sold the edition as old paper for $68. Clear profit $68, a good deal for poor young doctors. Such financial successes I had many in my life. Another book of mine, also out of print, of those times is "Dentition and its Derangements," 1862. It is queer all my books are out of print, with the exception of my "Therapeutics," which my kind-hearted publishers say may still be had.

From what I have been told to-night, and several times lately, I am to conclude that it is a common belief that I had a good deal to do with the development of pediatrics as a pet study in the profession, and as a subject for instruction all over the land. It is said I had my finger in most pediatric pies. It is true, in spite of unspeakable stage frights, I began to lecture very early, even in the spring course of the College of Physicians and Surgeons in 1857, and then 1860, as what they call a professor, in the New York Medical College. I also attached myself to a children's service in the newly established German Dispensary in 1857. Indeed I had the ambition that if ever the history of pediatrics in the United States would be written, my name should not be absent from its pages.

My merits, however, have been overrated, I am sure. But as an excuse for the mistakes made in my favor, I may say that I have been very fortunate in many respects. Mind, I was the first in the field when most

of you had not even the foresight of being born. Then I could recognize early how little had been done in America; and moreover all sorts of facilities were given me. As early as 1860 I could speak, long before I published my papers in the *American Medical Times*, on diphtheria in a discussion of the Academy of Medicine, simply because it had been my luck to see many cases and not to overlook them. For they were not quite so rare as they were believed to be. Indeed, their presence was denied by most. One of my warmest friends—at least I thought he was—was reported to say that week, but that week only: "I always thought Jacobi was an honest man. How the world is given to lying!" It so happened, however, that a week after the discussion alluded to a great many cases were reported.

Besides, the profession of New York, and of the State at large, was, as I think it is to-day, unprejudiced, anxious to learn even from the young who had facilities, and afforded me many more to learn and to teach. It gave me any and every opportunity for work, and many places of honor, showed me implicit confidence, and enabled me to use my influence in favor of young men whom I knew or believed to be willing and able to work. While I was busy myself, I could encourage others to work and to come to the front in pediatrics and otherwise. That is perhaps the best I have done in my life. Never has a foreigner, a young man, been treated with so much consideration, regard, and favor as the man who is speaking to you has been treated by the democratic generosity of the medical profession of America. And you here, all of you, form no exception. I am the more grateful for all I have received from you and from others lately, the less I may have the claim of having worked, though ever so successfully, in limited lines, or ruts perhaps, of a narrow specialty. I always was a general practitioner.

Indeed, the most important factor in active medical work, both curative and preventive, is the general practitioner, and among his class the pediatrist. His responsibility is the very greatest, his duties are the most serious. The questions of feeding at different ages, and of educating the well and the sick, the bright and the idiotic, must be answered by him. His domain is at the same time hygiene and pedagogy. The prevention of constitutional disorders, such as rickets and scrofula, and of infectious and contagious diseases such as scarlatina, measles, diphtheria, tuberculosis, and syphilis, are his studies and his duties. Whatever concerns the future citizen of the republic he is responsible for. In the performance of these duties he has to co-operate with nurses and mothers. I draw the line at grandmothers, with their hearts swelled with untimely sympathies and their pockets with indigestible sweetmeats. They are a constant danger. Mothers-in-law cannot hold the candle to these in point of dangerousness. One of the greatest dangers in the pediatrist's life—for that matter in that of every medical man—is overfeeding. In that respect I simply remind you of what you all know, that more infants are suffering from over- than from underfeeding. Still, the overfeeding of some adults is attended with equal danger. There are some of our trained nurses, who after a two years' course of instruction are bursting with learning. I met one lately, filled to her throat with Greek six-syllable terms, that ran a thermometer into an eight-weeks-old baby's vagina instead of the rectum. If you will look at the big-bellied textbooks they are compelled to swallow whole, you understand how those things can happen. What is wanted is more training, and less improvident, too technical learning. The tendency of our times is meddling with other people's business; that is why nurses are interfering with yours all the time. The public at large also is tempted to embark in the most dangerous dilettanteism of all, viz., that in medicine. The cheap yellow or otherwise colored newspapers, and the facility with which strictly technical books can be obtained, are a positive calamity. I know that a certain good text-book on the diseases of children, meant for the practitioner and the advanced student of medicine, is—to the advantage, I suppose, of the publisher, and of the retailer who pockets his commission, and to the detriment of the public—sold over the counter of a well-known New York milk-shop. This is a demoralizing measure which appears to be quite general, if I may judge from what happened to me two years ago. I at that time received the invitation from the secretary of a so-called congress of (alleged) mothers, in which I was told that I was considered competent to deliver an address before them at 3 P.M. on a certain day, on the physical education of children, and that they would refund my travelling-expenses to and from Washington, D. C., and also give me the permission to sell my books then and there.

Now, my friends, if there be anybody among you that thinks I am not at all pleasant in my remarks, but rather abusive, I could only reply that I was made that way. You see I must be consistent. If I were not, you would say: "Old age has changed him wonderfully."

That, however, reminds me of old Cicero, who was an intolerably garrulous man in the most polished Latin; he said—when he looked into the glass, I suppose—*loquar senectus*, old age is talkative. Unless I stop right here you will say I have grown old, and I want to do some work before I die, worthy, if possible, of the reception you have given me.

Of this reception what shall I say? Though I do not respond to your roll-call, you have treated me as if I belonged here; indeed, much better than that. You never honored a man as you honored me. That proves to me that I belong here after all. Indeed I find so many friends here that it is an impossibility not to feel perfectly at home. The honors your confer upon me prove only one thing to me, of which I am both glad and proud, viz., that you are firmly attached to pediatrics in the sense in which I always considered it, as a study full of interest in itself, of import to mankind, intimately connected with all branches of medicine, taking from them, giving to them, and combining the interests of biological research with the necessities and wants of the people. It finally proves one more thing, viz., that I have been able to gain your confidence, and that I have not lived in vain. Goethe says, that whosoever has succeeded in satisfying the best of his era has lived for all times. I thank you from all my heart.

AMERICAN ACADEMY OF MEDICINE.

Twenty-fifth Annual Meeting, Held at "The Shelburne," Atlantic City, N. J., June 2 and 4, 1900.

First Day—Saturday, June 2d.

THE meeting was called to order at 11 A.M. by the president, Dr. G. Hudson Makuen, of Philadelphia.

The secretary, Dr. Charles McIntire, read the minutes of the Columbus meeting.

The treasurer reported that the Academy was free from debt, but that the balance on hand was not so large as usual. The year had been marked by several losses from death.

Among the election of fellows to the Academy were: Drs. O. A. Emberly, of Massachusetts; Ella B. Everett, of Philadelphia; Thomas Snyder, of Niagara Falls; A. O. J. Kelley, of Philadelphia; J. Addison Joy, of Atlantic City; Judson Daland, of Philadelphia; W. R. Powley, of Atlantic City.

Drs. Risley and Carhart were appointed auditing-committee, and Drs. Connor, of Detroit, Jackson, of Denver, and Wilson, of Columbus, were appointed on the nominating-committee.

Report of the Special Committee for the Study and Formation of Principles Respecting Specialism and Respecting Advertising.—The secretary read the report of this committee, which first defined the word "specialism," as used by the committee, and presented the following propositions: (1) Specialism was not only desirable; it was unavoidable. (2) It was proper for a physician to seek to perfect himself in the direction of his greatest ability, even to the neglect of some other field of practice. (3) A specialist as well as the general practitioner could have a practice directly with his patients, or indirectly through consultation. (4) In his direct practice, a specialist ought not to be an exclusivist. (5) In his consulting-practice, a specialist stood in a different relation to his fellow-physician than did the general practitioner in consultation. He was rather a coadjutor than a consultant. (6) Specialism *per se* did not create discord in the harmony of professional intercourse. (7) The time to enter upon a specialty could not be predetermined by rule.

As to advertising: (1) No physician could escape advertising. (2) The true physician served humanity first; the earning of a livelihood being secondary. (3) Any method of advertising reversing this order was not to be commended. (4) Any method of advertising which only sought to inform the public that the advertiser was ready to be of service was permissible. (5) The above principles were fixed; their application varied with the environment. (6) Regulations restricting advertising should be equal in their action.

A symposium on "The Medical Aspect of the Home" followed.

The Essential Conditions for a Habitation to Develop and Maintain a Healthful Family Existence.—Dr. Rosa Engelmann, of Chicago, read a paper with this title. She stated that healthy family life depended upon health, character, intelligence, industry, frugality, mutual affection, forbearance, and the wherewithal to furnish a happy and healthy environment. Of supreme importance for the development and maintenance of these attributes was the separate-housing system. Among the essential conditions mentioned were fresh air and sunshine, adequate pure-water supply and good plumbing, healthful employment, healthful recreation, educational facilities. Lack of these conditions in large cities was considered, with the results, and the remedies therefor.

The Influence of Early Training of Manly and Womanly Qualities to Avoid Degeneracy.—Dr. J. Cheston Morris, of Philadelphia, furnished as a text an incident of a little girl poutingly disobedient, and the necessity of an early training in submission to authority. Acts spoke more effectively to children than mere exhortations or commands. Dr. Morris stated that the training in self-control must begin early in life, and that the reign of law and the influence of patient example was necessary to bring them about. Heredity, so-called, was often but the unconscious imitation of the parents' peculiarities by the very young. The lack of this early development permitted many forms of degeneracy, hence the importance of this early training.

The Influence of Medical Supervision of Children in their Homes.—Dr. J. Madison Taylor, of Philadelphia, read this paper. He said that the child was supposed to be capable of satisfactory development if allowed moderately good opportunity and environment, and was seldom or never systematically directed in its physical growth or development. The consequence was that very many faults of both mind and body were acquired, many of which seriously affected the subsequent activity of the child. He stated also that no attention was paid to the mating of the parents, as was done in the case of domestic animals, and consequently many faults of inheritance or heredity showed themselves. It was the purpose of the paper to call attention to these facts, and to demonstrate that if an intelligent direction was given to the growth and development of children these early faults could be corrected. He said that the province of the physician was limited, as yet, to the relief of actual illness and to repairing the effects of disease. If he were only encouraged to direct the growing child, his position as an apostle of preventive medicine would enable him to accomplish infinitely better results than merely the repair of damage. He then discussed the question of motherhood and the difficulties which arose from the lack of knowledge of those things which constituted a good mother. He stated that the first thing needed was that mothers should realize that the best specimens of human beings were not likely to come from haphazard up-bringing. He thought it safe to assume that skilled direction from a medical adviser would soon become recognized as of the greatest importance, and that the children of the poor should be provided with opportunities to receive skilled physical direction. This could be done only by educating the public to realize the importance of this fact, and by securing the co-operation of teachers of all grades in furthering such work.

School Hygiene and Medical Inspection of Schools.—Dr. W. M. Carhart, of New York, read a paper on this subject. He said that school life should be harmonious with and supplementary to home life. The growth of the child in bodily vigor, in strength of character, and in intellectual attainments should be as continuous at school as at home. School hygiene was divided into: (1) Hygiene relating to the personal habits of the child: necessity for cleanliness of both body and clothing, the avoidance of infection, and the exclusion of contagious cases. Vice had a physical basis; vicious habits should be discovered and corrected. (2) Hygiene in relation to methods of instruction. All children were not alike, and should not be taught as if they were. Backward and dull children needed special care. An inattentive child, usually defective in special senses, may possibly be slightly deaf. The human eye was going through the period of adaptation to the needs of the twentieth-century civilization, and in the interval asthenopia was a necessity under the modern methods of culture; the result was that weak eyes were permanently damaged and developed into myopia and astigmatism. (3) Hygiene in reference to the school environment. In this connection the writer stated that school buildings should be healthy in location, with adequate playgrounds, well furnished and well built, and with dry cellars. Good ventilation and clean rooms and lavatories with modern plumbing were also necessary. Desks and seats should be adjusted to the size of children.

Defectives and Delinquents Inside and Outside the Family Circle.—Dr. James W. Walk, of Philadelphia, gave in this paper the sociological definition of defectives and delinquents. The influence of defectives upon other members of the family circle was considered, as was also the influence of aggregate life (in hospitals, asylums, etc.) upon defectives. The influence also of family life upon defectives was spoken of. Delinquents and their environment were discussed in a similar manner. The author stated that efforts to benefit defectives and delinquents should be consistent with the welfare of society in general.

The Relation of the Habitual Use of Alcoholic Intoxicants to the Sanitation of the Home.—Dr.

J. W. Grosvenor, of Buffalo, read this paper. He considered the effect of the use of intoxicants on the moral character, intellectual development, and physical integrity of the inmates of a home. Two remedies of value for the relief of the unsanitary condition of the home were suggested—education and law. The writer considered that the enlightenment of the public along all sanitary lines was incumbent upon all boards of health. In the conservation of public health the medical profession had an important position. It was the opinion of the writer that the physician should not only by precept teach the danger of alcoholic intoxicants, but place himself and his home outside the use of alcoholic stimulants of every description. The clink of the inebriating cup should not be heard at his festive board.

The Hygiene of Vision in the Home.—Dr. S. D. Risley, of Philadelphia, read this paper. He described the family living-room—its origin, pleasures, and evils. The natural and artificial lighting of the home were spoken of, and the importance of sufficient and suitable illumination of the home in conserving the general health and vision of the family was emphasized.

The Physician's Influence in Regard to Vacation Schools.—This paper was read by Dr. Helen C. Putnam, of Providence, R. I. She said that inventions and municipalization had altered the popular minds that free schools were originally planned to supply, and that to-day more should be done for citizenship, character-building, and physical development. In the speaker's opinion liberally educated medical specialists were needed in this readjustment. Reference was made to vacation schools started by philanthropists to protect from their environment the children living in the poorest wards, and developing into a permanent institution of direct influence upon educational systems. In these schools no books were used; pedagogic excursions into the country were made; manual training by wood and iron work was taught; the æsthetic development of music, color work, out-door sketching were encouraged, out-door gymnastic games were indulged in, and self-government obtained in place of autocratic.

President's Address: Some Measures for the Prevention of Crime, Pauperism, and Mental Deficiency.—The president, Dr. G. Hudson Makuen, of Philadelphia, in his address stated that crime, pauperism, and mental deficiency were on the increase and were beginning to be a menace to our national life. The causes of this increase were many and complex. Civilization had not progressed uniformly. Many of its most important advances had a tendency to swell the ranks of the defective, delinquent, and dependent classes. The survival of the unfit had become our motto, and the fact that hand-in-hand with their survival went their reproduction had been ignored. The natural resources of our country had attracted foreigners in great numbers and in all conditions of mental and physical depravity; hence the necessity for restricted immigration, more stringent marriage laws, and, in carefully selected cases, the entire removal of the power of procreation. The evils of promiscuous almsgiving and promiscuous dispensary service were also pointed out, and attention was called to the fact that real charity was that which helped people to help themselves. He also touched upon the evils of institutionalism in the care and treatment of the defective, delinquent, and dependent classes, and suggested, as a final measure for the prevention of crime, pauperism, and mental deficiency, the widening of the scope and influence of our methods of education. The object of education should not be so much the acquirement of knowledge as the development of character and of brain power, of which the acquirement of knowledge and its effective application were the natural corollaries. Every possible avenue to the brain should be utilized in education. The action and effects of the various kinds of mental and physical training, and the best methods for their application, should be studied. Thus could be demonstrated the important fact that the moral nature was as capable of development as the intellectual nature; and that muscle training in all its varied forms was an essential factor both in the formation of character and in the development of brain power.

Second Day—Monday, June 4th.

At the opening of the session the nominating-committee announced the following nominations: *President*, Dr. S. D. Risley, of Philadelphia; *Vice-Presidents*, Drs. C. M. Culver, of Albany, Rosa Engelmann, of Chicago, G. G. Groff, of San Juan, W. C. McClintock, of Detroit; *Treasurer and Secretary*, Dr. Charles McIntire; *Assistant Secretary*, Dr. Alexander Craig, of Columbia, Pa.

The above candidates were elected.

The selection of time and place of meeting was placed in charge of the council.

How One College Endeavors to Teach Social Health Problems.—Dr. Charles McIntire, in this paper, gave Billings' definition of hygiene, which was approved by sanitarians and included sociology. It was stated that Lafayette College offered an elective on sanitary science to the seniors, and the paper outlined the course given, with the purpose of presenting the social problems having an influence upon the public health.

The paper of Dr. E. Stuver, of Fort Collins, Colo., on "The Home and the School," was read by title.

The discussion of the papers read in the symposium on "The Medical Aspect of the Home" was taken up at this point.

Dr. Tuckerman, of Cleveland, in reference to this topic said that they had in Cleveland just succeeded in the adoption of medical inspection in schools. He cited a case in which a teacher having sore throat had gone into her school, and as a result in two weeks' time five children had died and forty cases of diphtheria had developed. In reference to Dr. Walk's paper on "The Treatment of Defectives and Delinquents," Dr. Tuckerman approved of the suggestion of the president of asexualization, believing that these male defectives coming to puberty were as dangerous as wild animals let loose in the community.

Dr. Grosvenor, of Buffalo, referring to one of the papers on the parental teaching of children, spoke of a custom of some parents, of teaching their children to call their parents by their first names. He had observed this custom in his own city. He feared that if a strong protest was not made against it the custom would become more prevalent.

In the discussion of the paper of Dr. Engelmann, of Chicago, Dr. Knopf, of New York, thought that while the separate-housing system for habitation was very desirable, the suggestion seemed impracticable. He thought the solution of the problem could be more easily secured in the improvement of tenements, and the destruction of old tenements and the erection of new ones with proper appliances of sanitation. In reference to the early training of children he suggested that the whole problem might be solved by adding to the higher schools for girls a chair of practical motherhood.

Dr. Connor, of Detroit, thought that the great underlying principle of the papers and discussion was to attempt to find out the weak methods in our art of training men.

A paper entitled "A Few Notes Concerning the Relation of the Academic to the Medical Course," by Dr. Howard S. Hansell, of Philadelphia, was read by title. The purpose of the paper was to advocate the admission of the college-bred man into the second year of the medical course.

The Opportunity of the Small Medical College.—Dr. Bayard Holmes, of Chicago, read this paper. He said that the tendency toward large classes was not consistent with good pedagogy, and that small classes and individual supervision were possible in the small school. As requisites were mentioned the following: A few teachers and leaders of men, with time and adequate salary; suitable buildings and laboratory equipment; a small hospital under the complete control of the college; a well-selected working-library, containing the material for the study of medicine; intimate relations between the various departments; a curriculum granting freedom to teacher and student. All of these requisites it was stated were possible to the small college.

Neglected Clinical Opportunities in American Medical Centres.—This paper was read by Dr. S. A. Knopf, of New York. He endeavored to show that in spite of the vast progress many of our medical college had made during the past year toward a more thorough curriculum, clinical teaching was still very deficient, not from lack of clinical opportunities, but from the neglect to utilize those available. The writer contended that the essentials for a college graduate leaving college, feeling that his clinical teaching, if not quite equal to that of any hospital graduate, was at least nearly so, were: (1) A co-operation of all the medical colleges located in one medical centre for the purpose of a general and equal utilization of all the clinical material of their city; (2) the appointment of every physician and surgeon attached to a subsidized hospital as a clinical teacher independent of college affiliation, and the payment of a reasonable fee to these clinical teachers for their services rendered as teachers to the students; (3) the suppression of all didactic lectures for second, third, and fourth year students during the morning hours; (4) the obligatory presence of every second, third, and fourth year student in his capacity as senior or junior externe at the clinic or at the daily hospital visit of his teacher; (5) the keeping by the clinical teacher of a record of attendance and work, to be counted in the final examinations.

Psychology as Preliminary to Medical Education.—Dr. W. J. Herdman, of Ann Arbor, Mich., read this paper. He stated that normal anatomy and histology were essential to a right understanding of normal physiology. Psycho-physiology must be known if we would correctly interpret psycho-pathology and create a rational psychotherapy. The speaker considered that at the present day a very small percentage of candidates for the degree of Doctor of Medicine had pursued a systematic study of physiological psychology. Such knowledge was claimed to be essential to a right understanding and direction of educational methods, since faulty methods of education resulted in disease. Functional disorders would be much better understood and more rationally treated were the physician well trained in psycho-physiology. The mental element of disease was largely-ignored by the practitioner of to-day, and in this soil left uncultivated by the scientific physician faith-cures and other noxious weeds took root and flourished. He believed that a broader preparation was needed to fit the physician to take possession of this field.

Dr. Elmer Lee, of New York, said that Dr. Herdman's paper was along the line of his own observations, and upon which some words of his own had been published. The fact that there was a mental state in the practice of medicine was too little understood and too seldom successfully used.

Dr. Knopf, of New York, advocated the including in the curriculum for senior students the study of hypnotism, so that this important therapeutic agent might be taken out of the hands of those who by their wrong-doing depreciated the value of hypnotism as a therapeutic agent.

Dr. Connor, of Detroit, thought that Dr. Herdman's presentation was a clear demonstration that what he called psychology was simply a refined part of physiological and pathological processes.

Some Experiences of a Volunteer Surgeon in the Philippines.—Dr. H. P. Ritchie, of St. Paul, late captain and assistant surgeon in the Thirteenth Regiment Minnesota Volunteer Infantry, read a paper on this topic. He said with reference to the transport service that the causes of complaint and discomfort during the first expeditions were unnecessary, as shown by the pleasant experiences of the home voyage eighteen months afterward. The effect of the campaign before Manila upon the future health of the troops was considered. The condition of Manila at the time of its occupation, and its transformation under American rule, were described. The climate was discussed, and the diseases among the troops were briefly considered, with their prophylaxis and their danger to the civilian. The paper closed with a plea for the establishment of schools for instruction in tropical diseases.

"Good Form" in Professional Cards.—Dr. Charles McIntire, of Easton, Pa., in this paper referred to the source of gratification to the fellows of the Academy of Medicine that there had been almost no necessity to discuss the individual actions of its members. Last year an exception was taken to the wording of a professional card, and the secretary was instructed to correspond with the member whose card was criticised. The present paper was the result of that correspondence, classifying a number of professional cards from various parts of the United States.

The Desirability of a Medical Editor on the Staff of the Daily Newspapers.—This paper was read by Dr. Walter L. Pyle, of Philadelphia. As an indication for this need the speaker called attention to an article recently appearing in the New York *Herald* entitled "Sleep Cure for Nervous Dieases." This cure consisted of "eight grams of bromine every two hours in a glass half full of water." It was further stated in this issue that the discoverer of this rest cure maintained that rest—absolute, prolonged rest—was the one thing which persons suffering from nervous disorders stood most in need of, and that they could obtain the rest through the agency of bromine better than in any other way. It was suggested that the medical member of the newspaper staff would prove satisfactory, particularly in editorial work upon such subjects as food adulteration, water filtration, and quarantine. The offensive medical advertisements might be corrected by the medical editor, who should act as a censor on all notices of a medical nature.

Domestic Hygiene.—Dr. Elmer Lee, of New York, read this paper. He said that sickness, suffering, and death were the most expensive factors in human existence, and that each human being enjoyed or forfeited his rights exactly in proportion to his use or abuse of them. Air was referred to as the most important factor of all the agencies which contributed to animal life; everywhere it was adapted to the creature who rightly used it. A drink of cool water had virtues superior to any and all life-saving agencies. Mineral waters, either natural or artificial, were less wholesome, in the writer's opinion, than water which held no minerals in solution. The rainfall was the source of pure water. Carbonic acid gas was an ingredient

of dangerous nature, and was the basis of the effervescing waters. This gas, it was stated, was a deadly poison to all animal life, and was at all times a waste product in the blood. Water was stated to be man's sweetest and safest drink, and if rightly used would in itself largely help to extend his life well toward the century mark. In the matter of food, in the author's opinion, there were ample proofs to show that it was not a greater variety in vegetable, flesh, or mixed diets consistent with health that was needed, but rather the use of any diet in moderation. The subject of human feeding was regarded as the one most neglected in popular education, and it was incumbent on mothers to form health kindergartens, first for their own information and secondly to lead and direct their children in the light.

New Instruments.

PRACTICAL HINTS FOR *X*-RAY WORKERS.

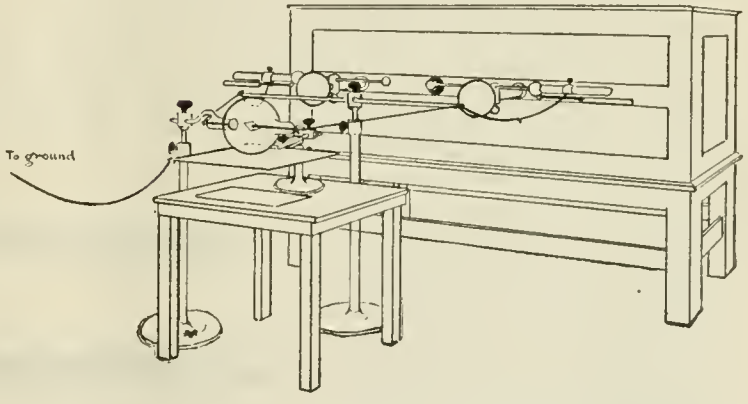
By GUION THOMPSON,
NEW YORK.

THE choice of an *x*-ray apparatus is usually perplexing to the person buying it for the first time and who is unfamiliar with the results and methods of operation of the different styles of apparatus, and, after making a choice, many give up on account of failure to get good results. It is not my intention to consider the advantages and disadvantages of different apparatus, but to give my opinion as to which is best, and how to operate it properly, and this opinion is arrived at by experience and study in electrical science.

The static machine is the ideal generator of electricity to operate the *x*-ray tube. It should not be smaller than one of eight thirty-inch revolving plates, and should be run by a motor capable of a speed of about six hundred revolutions per minute. The plates should be of glass of the best insulating qualities obtainable, and the machine should be of the type known as the "Holtz-Influence" and not the "Holtz-Toepler." The "Holtz-Toepler" machine has small metal discs on its plates for the purpose of making it self-exciting, and these discs cause the machine to generate a pulsating current that will often reverse while the machine is in operation. In the "influence" type the electric current is steady and generated in an even flow that will not reverse unless it is purposely made to do so. The tubes should be those that are made to be used with the static machine, and must have their terminals far apart at opposite ends of the tube. The body of the tube should be a sphere, and the centre of the anode disc should be exactly in the centre of this sphere. The cathode terminal is a cup-shaped disc whose concave face should focus exactly on the centre of the anode, which is set at an angle of 45° to reflect the cathode rays focused on it to the side of the tube. The cathode cup and the anode disc should not anywhere approach nearer than within one-half inch of the glass walls of the tube. When nearer than this, liability of the tube to puncture is increased. Have a proper adjustable stand for holding the tube in any desired position and another to hold a thirty-inch porcelain or ebonite rod, with hooks or clips on each end. This is extremely handy—half the time absolutely necessary—to support the conductors from machine to tube. These conductors have small hooks at each end, one to connect to the eyes at the external terminals of the tube and the other to connect with the "interrupters" at the terminals of the machine.

Start your machine and see that it is charged and generating, and determine which is the positive pole. To find this, draw the sliding poles about half an inch apart and observe the spark; it will be of a violet color with white tips at each end. The end at which the white tip is largest is the positive side of the machine. Now attach the interrupters, leaving them wide open, and hook on the conductors.

Adjust the tube in the stand so that the anode reflects the cathode toward the point from which you wish to observe, and see that the tube is so placed that the anode can be connected with the positive of the machine and the cathode with the negative without crossing the conductors; hook them to the tube in this position, using the porcelain rod to support and separate them. Close the interrupters and draw apart the sliding poles of the machine. Before they are an inch apart the spark stops and the tube lights up faintly a palish green all over the glass in front of the anode disc, while back of it is shadow, faintly tinged with violet. The tube is "low"; its vacuum is low. Open the positive interrupter so that you have a spark gap in the circuit on the anode side of the tube. Two or three hours' use of the tube connected in this manner will bring it up, especially if it is "shut off" frequently for short rests. These low tubes can be used for such light work as making radiographs of the hands, etc., until they come to their best working condition, when they should be kept for heavier and more



difficult work. Close the sliding poles of the machine to within about a quarter of an inch of each other; open both interrupters and remove the conductors from the tube, and try another. Connect up the same as before, close the interrupters, and draw the sliding poles slowly apart. The spark lengthens out perhaps to eight or ten inches before the current passes through the tube, and when it does there is only a faint and fluttering tinge of light on the walls of the tube, with here and there bright oval spots of greenish light that come and go all over the walls of the tube. The tube is said to be too "high." To bring it down, open the interrupter at the negative terminal of the machine so that there is a spark gap in the circuit at the cathode side of the tube. If this does not bring it down in a few minutes, heat the tube carefully and evenly with a spirit-lamp or Bunson-burner gas flame, and it will work beautifully. If, when we try to start a tube, it stays perfectly dark and shows no action whatever, it may possibly be brought down by persistently working at it, but it had better be re-exhausted, as it will always be a nuisance when most wanted if left so high.

Disconnect this tube and connect up another. If, when you draw apart the sliding poles, the spark stops when it gets about four inches long, and the tube lights up with a clear, even, bright glow on the hemi-

sphere in front of the anode disc and remains dark behind it, then you have an almost perfect tube. The fluoroscope will show more finely how a tube is working, and each tube should be examined with it for penetration, focussing qualities, etc. A tube running without a spark gap in circuit will give the finest definition. When using the fluoroscope it will be noticed that a tube will appear to give more light with a spark gap in circuit than without, but with less clearness and definition. For many reasons it is best always to run the tube without any spark gaps at all, if possible. The spark causes the current passing through the tube to be an intermittent one of exceedingly fast periods, and as the tube is of a certain resistance it allows just so much current to pass whether with or without the spark gap, and as the current is varied in any given tube so are the rays emitted by that tube. Therefore it is clear that the spark gap cannot increase the *x*-rays generated by any tube, but by interrupting the current so that it passes in flashes through the tube, each flash becomes brighter than the light of a continuous current, because in it is stored the energy of the dark periods between flashes.

These rapid, bright flashes affect the eye so that there appears to be a brighter light than when they are absent; but in making a radiograph we have to increase the exposure of any tube if we have a spark gap in circuit, and the exposure increases in proportion to the length of the spark gap, proving that the spark gap absorbes energy, which of course it must do. Also, when we make a radiograph with a spark gap in circuit we lose definition in the shadowgraph; this is seen also in the fluoroscope, and is caused by the rapidly pulsating current inducing an opposite potential in the tube at each flash, which has the effect of "upsetting" the focusing of the cathode rays on the anode disc and causing them at each flash to focus at a different spot, so throwing the shadow caused by each flash at a slightly different place, the whole appearing to the eye, or coming out on the sensitive plate, as a blurred shadow. The spark also increases the danger of burning the patient a hundred-fold, as the strong pulsating currents it causes set up opposite currents and charges of electricity in near-by bodies by induction from the tube. These currents have "burned" patients badly at times, and an example of how strongly a patient will become charged under a tube being operated in this manner is shown by the shock received on touching the subject after a few minutes' exposure. If you will always use a thin metal screen between the patient and the tube, and ground the screen by connecting with gas or water pipes, you need never fear "burning" the patient. The screen is inductively acted on instead of the patient, and the currents that would make a "burn" are carried off to earth. A thin aluminum screen is the best of metal screens, as it is less opaque to the rays than other metals. A damp cloth may also be used—the water acting as the conductor.

When running a tube without any spark gap in circuit it is almost needless to use the screen, but the safest practice is always to use it, as any moment during an exposure may necessitate a spark gap to control the action of the tube.

In making radiographs, the patients should be in as restful a position as possible, so that they may have every advantage for keeping still. Lay the sensitized plate, emulsion side up, on a perfectly flat surface, and let the region to be taken rest upon it. The plate should be in a light-proof envelope to protect it from the action of ordinary light. Place the tube above the plate and patient so that its rays shall pass through the subject to the plate. The distance of the tube from the plate is governed by the thickness of the subject being taken, and should always be far enough away not to distort the shadow unduly. The exposure can be judged only by watching the light with the fluoroscope, and experience is the only instructor here. Be careful that no plates are near by—not even in the next room—or you will wonder what makes so many of your plates develop "fogged," or altogether black. The rays from the tube will go through walls and furniture and spoil many a plate if you are not careful. You cannot keep them far enough away. Do not use a fluorescent screen with your plates. It shortens the exposure but kills definition and sharpness in the radiograph, and this result is most unsatisfactory.

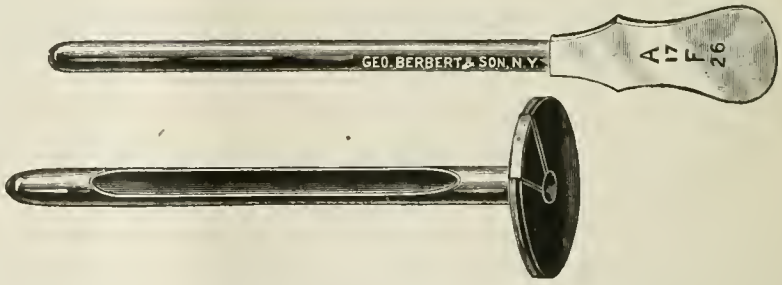
289 Fourth Avenue.

A NEW URETHROSCOPE.

By FRED. J. LEVISEUR, M.D.,

NEW YORK.

This instrument, which is destined for the examination and treatment of the pendulous part of the urethra only, consists, like the ordinary urethroscope, of a hollow tube with disc and obturator. The tube is closed at the distal end and fenestrated on the side, the slit extending to within a quarter of an inch of each end. The obturator has the shape of an ordinary straight sound, and fits loosely in the tube. A V-shaped mark on the disc indicates the position of the fenestration. The instrument, well lubricated, is introduced with the obturator *in situ*. When the latter is withdrawn, a considerable portion of the mucous membrane becomes visible, slightly bulging into the lumen of the tube. The picture thus presented markedly differs from that which we are accustomed to see with the ordinary urethroscope, where a small cone of the mucous membrane only is visible at the time, and the rest is brought into view by gradually withdrawing the tube. With this instrument the remaining three longitudinal sections of the urethra can be inspected by introducing the obturator—also lubricated—each time and rotating the urethroscope through an angle of 90°. Before the removal of the instrument from the urethra the obturator is introduced again.



The examination can be made either with direct or reflected light, though I have found the direct light the best. The introduction of the instrument is not more painful than that of an ordinary sound, and there is no danger of injuring the mucous membrane.

Pathological conditions situated at the distance of one-half to one inch from the meatus can be seen especially well. It is also possible to locate the position of a stricture by noting some additional bulging of the mucous membrane in front as well as behind the affected spot. What renders the picture a particularly interesting one is the presence of the numerous circular folds, which give the mucous membrane a finely striated or rifled appearance.

640 Madison Avenue.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 30, 1900:

	Cases.	Deaths.
Tuberculosis	123	133
Typhoid fever	29	7
Scarlet fever	95	4
Measles	202	24
Diphtheria	285	35
Laryngeal diphtheria (croup)	4	7
Cerebro-spinal meningitis	0	6
Chicken-pox	15	0

Law for the Control of Milk Dealers in Japan.—The following is a brief translation of the law recently promulgated for the control of dealers in milk:

Art. II. The specific gravity of milk shall be from 1.028 to 1.034 in the case of new milk and from 1.032 to 1.038 in the case of skimmed milk; in both cases at a temperature of 15° C. In new milk the quantity of fat must exceed 2.7 per cent., and in skimmed milk it shall not be less than 0.5 per cent.

Art. V. Dealers in milk are not allowed to obtain milk: (1) from cows affected by contagious diseases, such as cattle plague, rabies, jaundice, dysentery, fever, etc.; (2) from cows being medically treated with powerful or poisonous drugs; (3) from cows which have calved within the space of one week.

Art. VI. Dealers in milk are forbidden to use porcelain vessels glazed with zinc, copper, bronze, or other injurious materials, or vessels of iron coated with materials containing lead.

Art. VII. No milk dealer shall undertake the sale, transport, or preservation of sour milk; milk which is curdled or of bitter taste, or is of blue, red, or other unusual color; milk mixed with other materials.

Art. XII. Dealers in milk shall not allow persons suffering from consumption, leprosy, syphilis, or other contagious disease to handle milk or milk products or vessels used for holding or measuring the same, or to enter into a place where such articles are handled.

Art. XIV. The local governor may despatch officials to inspect the cows owned by milk dealers, and upon finding any diseased animal may brand or mark its horn, or affix a ring to its ear.

Art. XVIII. Offences enumerated below shall be punishable with a fine not exceeding twenty-five yen: (1) Dealing in milk without obtaining official permission; (2) contravention of Article V.

Art. XIX. Any person failing to inscribe the quality of milk on the vessels containing it, or to segregate a diseased cow or cows, shall be liable to a fine not exceeding ten yen.

Art. XX. These regulations shall come into operation from the 1st of July in the thirty-third year of Meiji (1900).

Definition of the Word Physician.—Dr. Murray, of Oxford, England, and the editor of the *Oxford Directory*, thus defines the origin of the word physician: The word physician was taken by us from Norman-French in the thirteenth century in the form fisicien, and in its present sense of practiser of the healing-art, medicus, the only sense which it had in contemporary French. It has never had any other sense in English, though one or two writers have expressed a desire to abolish this and to convert the word back to the sense of Latin physicus (Greek φυσικὸς), student of nature, naturalist, natural philosopher. Hume did this, but only as an etymological fancy. In French it has been different: médecin has successfully ousted physicien, and the latter in modern French since the sixteenth century has meant physicist. If you will turn to Du Cange's "Lexicon of Mediæval Latin," you will find that the regular mediæval Latin sense of physica in medicine is medicina, and physicus equals medicus. But in classical Latin and as late as the Latin lexicons come down, *i.e.*, to the fifth century or so, physica in Latin literature meant natural science, and physicus a physicist. What you have to do then is to show how the Latin physicus and physica passed between the fourth and fifth, and say the eighth or ninth centuries—during the very midnight of the middle ages—from the ancient to the mediæval and modern sense. This is an inquiry that lies far away behind the scope of an English or even a French dictionary; it is part of the general history of the Latin language during the period of the break-up of the Roman Empire and civilization, for which perhaps no materials exist, and all that can be said is that the change took place and was a very natural and intelligible one. I have little doubt that even in the third century the common peasant of Italy or Gaul thought a physicus must know something about the influence of stars and planets and mysterious influentias or influenzas generally, and about the position of bones and virtues of herbs, the only practical use of physica to him, and so thinking the physicer a medicus called the medicus a physicus. Does not the ignorant nineteenth-century Englishman call a drug-seller a chemist for the same reason, and does not the drug-seller find it profitable to call himself a chemist, which he is much less than a baker or whiskey maker is? Well, when the Roman civilization perished all the literary class (as a class) perished, and the peasant survived, and his Latin became the language of the modern world. He did not call in a medicus to use his medicina to cure his bad "crures" or his aching "caput," but got a physicus with his physica (fisicus and fisica he wrote them when he could write) to attend to his "gampas" (pins or hockey sticks), or his "testa" (shell or cocoanut). The substitution of physicus for medicus is the only part of the great revolution, but it is a long way anterior to English, and to the Englishmen of thirteenth century who accepted physicien or fisicien as quite the fashionable, courtly learned title for their own leche or leech. Of course modern etymologists, going back to the original Latin and Greek sense, are apt to think the words ought to have the original sense, which is to undo history and pull down the Tower, St. Paul's, and Westminster, to say nothing of Cannon Street station, in order to restore Roman London. (They do so at Athens and Rome.)—Meeting of General Council of Medical Education and Registration in England.

Endemic Centres of Plague.—In China, in the Himalayas, in Mesopotamia, in Persia, in Arabia, and in Tripoli centres of plague have long been known to exist and have always been regarded as possible sources of danger in the future, and recent inquiry has further brought to light the fact that similar foci of the disease have, at least for some years past, been more or less active in Siberia, in Mongolia, and in Central Africa. Plague has for a long period been endemic in Yunnan, the province in the extreme south-west corner of the Chinese empire, closely bordering on Burmah on the west, and extending northward toward the frontiers of Tibet. . . . A Chinese gentleman has quoted in the pages of *Nature* a passage in a Chinese work which he found in the library of the British Museum, and which he says "bears witness to the much earlier occurrence of the pest in Yunnan, insomuch as the author, who was born in 1736 and

died in 1809, speaks of his contemporary dead thereby thus: "Shi-Tan-Nan, the son of Shi Tan, now governor of Wang-Kiang, was notorious for his poetic gift. . . . Then in Chan-Chan [in Yunnan] it happened that in the daytime strange rats appeared in the houses, and lying down on the ground perished with blood-spitting. There was not a man who escaped the instantaneous death after being infected with the miasma, Tan-Nan composed thereon a poem entitled 'Death of Rats'—the masterpiece of his; and a few days after he himself died of this queer rat epidemic." The close association of this peculiar behavior of rats with the prevalence of plague in man observed in the same province in recent years makes it almost certain that the disease here referred to was plague, although no symptoms are mentioned by which it can be finally identified.—*Journal of Tropical Medicine.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended June 29, 1900:

		Cases.	Deaths.
Smallpox—United States.			
District of Columbia, Washington	June 16th to 23d	14	
Illinois, Chicago	June 16th to 23d	7	
Indiana, Indianapolis	June 15th to 22d	2	
Kansas, Wichita	June 16th to 23d	3	
Kentucky, Covington	June 16th to 23d	12	1
Louisiana, New Orleans	June 16th to 23d	16	7
Shreveport	June 16th to 23d	3	
Massachusetts, Fall River	June 16th to 23d	5	
Lowell	June 16th to 23d	1	
Michigan, Grand Rapids	June 16th to 23d	1	
N. Hampshire, Manchester	June 16th to 23d	3

White Meat and Dark Meat in Dietetics.—In a recent series of articles published in a German medical journal Drs. Opper and Rosenquist deal with the opinion that has been accepted by many that white meats are more suitable for the sick owing to greater digestibility and the presence of less uric acid and nitrogenous extractives. This belief is shaken by the analyses made by the medical men referred to, which show that while white meats, such as poultry and fish, do in certain cases contain less extractive and nitrogenous derivatives, the average amount does not appreciably differ in dark and white meats, such as poultry, veal, beef, pork, mutton, etc., to make either preferable. They point out that the only way of limiting the ingestion of these deleterious extractive and nitrogenous substances is by diminishing the amount of meat taken rather than by forbidding dark meats. They also assert that among the extractives present in meat, the most important ones are by no means harmful if taken in small quantities as is ordinarily done. The same holds good as regards the other organic extractives which are nitrogenous.—*Public Opinion.*

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

SOME CLINICAL OBSERVATIONS ON LUPUS ERYTHEMATOSUS; THE PATHOLOGY OF LUPUS ERYTHEMATOSUS.[1]

BY J. A. FORDYCE, M.D.,

AND

O. H. HOLDER, M.D.,

NEW YORK.

A NUMBER of the so-called chronic inflammations of the skin, whose clinical manifestations are so unlike that we do not hesitate to give them distinct and definite names, present very similar microscopic pictures. In lichen planus, psoriasis, and other superficial affections, we find in the papillary area of the derma an accumulation of lymphoid cells accompanied by a proliferation of the prickle-cell layer of the epidermis with varying degrees of parakeratosis. Some cause with which we are unfamiliar operates either through the blood stream or possibly through the skin from without, exciting an outpouring of leucocytes and the subsequent changes which take place. The pathogenic agent not being sufficient to destroy the implicated tissues, complete restitution takes place, and little or nothing remains to show that a struggle has occurred between the tissues and the foreign organism or poison. This happy outcome is not often met with in the deeper-seated infectious granulomata, for even after the involution of such lesions without ulceration, more or less destruction of the connective-tissue elements of the derma takes place with resulting atrophy.

In lupus erythematosus, which is under consideration in this paper, we have a chronic inflammation of peculiar type, which, in the early stages of the affection, appears to be exclusively confined to the small vessels of the upper and middle regions of the derma. In its later stages the connective tissue undergoes a peculiar degeneration leading to a superficial but pronounced atrophy of the skin, the leading clinical feature of the disease (Fig. 1). The negative results which have followed attempts to find a local bacterial agent, as well as the failure of repeated culture and inoculation experiments, have led many clinical observers to the opinion that we have to do with a toxic agent which is carried by the blood current from some extra-cutaneous focus. The resemblance of lupus erythematosus to lupus vulgaris in its gross clinical features led many of the elder dermatologists to regard them as closely allied processes, if not actually identical. A more careful clinical as well as microscopical study of the two affections, however, showed them to differ in so many respects that they were, with few exceptions, looked upon as totally dissimilar diseases.

The fact that lupus erythematosus is at times associated with tuberculosis of the lymph nodes, the lungs, or other visceral tuberculosis, has prevented Hutchinson, Besnier, and others from accepting the view, until lately almost universally held in Germany, that they are in no respect related. Besnier and the majority of the French school uphold in the most emphatic manner the close relationship of the affection to the tuberculous process.

Boeck [1] in an elaborate article supports the same view. In his carefully tabulated record of thirty-six cases he finds pronounced symptoms of tuberculosis in two-thirds of them, and a family history of tuberculosis in half the remainder. It would not be possible, as he well states, to find so large a percentage of tuberculosis in an equal number of the adult population.

Roth [2] has collected from literature records of about two hundred and fifty cases of lupus erythematosus, and in one hundred and eighty-five of them there was more or less pronounced evidence of tuberculosis. As tuberculosis frequently exists in a latent form which is difficult or impossible to recognize, it is not improbable that the percentage of such cases in connection with lupus erythematosus may be even greater than the statistics of Boeck and Roth would seem to show.

FIG. 1.—Lupus Erythematosus Discoides of Eight Years' Duration, Showing the Characteristic Atrophy. In addition to the lesions on the face there are three bald and atrophic spots on the scalp. The patient, aged thirty years, is a tailor, and though somewhat anæmic gave no personal or family history of tuberculosis.

In Boeck's opinion, the symmetrical outbreak of the disease is due to the action of the tubercle bacilli toxins on certain vasomotor nerve centres. The symmetry of the eruption is by no means a constant feature

[2] *Ibid.*, B. li., S. 3, 1900.

of the disease and may be susceptible of other explanations.

The absence of positive knowledge concerning the etiology of the affection under consideration has led to the most varied views as to its causation. It has been regarded as a tuberculosis; an inflammation produced by local causes in individuals of slight resisting-power; an angioneurosis; a specific infectious disease caused by the growth of micro-organisms; a form of skin tuberculosis produced by a species of bacilli supposed to differ from those found in the lungs and in lupus vulgaris; a neuritic inflammation of the skin, the result of the growth of the tubercle bacilli in the nerve fibres in analogy with the skin changes caused by nerve leprosy.

Fig. 2.—Lupus Erythematosus Disseminatus. The eruption began, two months after the patient became pregnant, as an erythema multiforme of both hands and forearms. The centre of the erythematous patches was marked by superficial atrophy.

As most of these theories have been shown to be untenable, an attempt is now being made by an increasing number of dermatologists to explain its frequent association with tuberculosis by the action of the toxins of the bacilli. Although difficult to demonstrate, the hypothesis is an attractive one and has much to commend it. The poisonous substances which result from the growth of tubercle bacilli are not well known. We have learned, however, from the experiments of Prudden and Hodenpyl, Vissman, and others, that dead tubercle bacilli when injected in animals are capable of producing tuberculous nodules ending in fibrosis. E. A. de Schweinitz[1] has shown that a crystalline substance which he obtained from pure cultures of the tubercle bacilli produced necrosis of the liver cells of guinea-pigs when injected in minute quantities directly into this organ, and in the skin of these animals when used subcutaneously. This substance, he is led to believe, is the temperature-reducing agent and is distinct from the fever-producing principle of the germ. We can only surmise, in view of our lack of positive knowledge, that certain cases of lupus erythematosus, when met with in conjunction with visceral or other tuberculosis, may be due to the action of the toxic products of the tubercle bacillus. The primary involvement of the blood-vessels, together with the symmetrical outbreak of the eruption in the majority of cases, favor the supposition that the causative agent is one acting through the blood stream.

[1] "Some Products of the Tuberculosis Bacillus and the Treatment of Experimental Tuberculosis with Antitoxic Serum." Reprinted from the Transactions of the Association of American Physicians, 1897.

The involvement of the flush area of the face, which is so frequently met with in this affection, can be readily explained by the slowing of the blood current and the diminished resisting-power which the paretic vessels offer to the hypothetical toxin.

It is not improbable that lupus erythematosus, like many other diseases in dermatology, may have more than one etiological factor; that it is not a distinct entity, but the result of the action of other agents than those formed by the bacillus of tuberculosis.

In view of our imperfect knowledge concerning the etiological factors in skin affections, we are not in a position to assert that all eruptions apparently alike must be due to a single cause. In the skin, no less than in other organs, we may have the same conditions caused by various toxic or bacterial agents; on the other hand, a definite pathogenic bacterium, as the tubercle bacillus, may give rise to symptoms more or less dissimilar, but which we are able to class in a single group by reason of our ability to detect the germ by the microscope or through culture or inoculation experiments. The supervention of the disease on local injury to the tissues, as in the case of frost bite, sunburn, etc., and on previous affections of the skin, like seborrhœic dermatitis, suggest that a purely local cause may, at times, be responsible for its occurrence. Atrophy of the skin has been observed to follow the dermatitis produced by the Roentgen rays without antecedent ulceration. Some observations which have recently been made in syphilis by one of us would seem to show that we may have in that disease an eruption closely allied in its clinical and anatomical features with lupus erythematosus.

The following brief clinical reports of some of the cases which have come under our observation are intended to illustrate a few of the types of the affection.

Case I.—Lupus erythematosus disseminatus disappearing during pregnancy. The patient, whose case has been previously reported,[1] developed two months after the beginning of pregnancy a symmetrical eruption of the dorsal surfaces of both hands and over the forearm not unlike an erythema multiforme. A very superficial but distinct atrophy appeared in the centre of the larger patches (Fig. 2). The margins of the eruption were only slightly infiltrated and no scaling was evident. The patient was again examined when almost at term, when all evidence of the disease had disappeared, except the atrophied spots, surrounded by a pigmented zone. She was seen again after her confinement, and stated that preceding labor she had had a number of convulsions from which she recovered.

We have in this case a suggestion at least that some form of toxæmia was responsible for the symmetrical erythematous eruption, and that the toxic agent was of such a character as to destroy permanently a portion of the connective tissue of the true skin. Although tuberculosis could not with absolute certainty be excluded, it is quite unlikely that it was present in view of the absence of all positive signs of the disease.

Crocker[2] has called attention to a variety of types of lupus erythematosus resembling papular, nodular, and diffuse erythemata, from which they were distinguished by their slow development, persistence, and tendency to spread at the margins. Similar cases have come under our observation in which the diagnosis was for a long time doubtful, and could be made only by excluding other conditions. The disseminate form of the disease not infrequently simulates polymorphous erythema in its evolution and distribution, and is at

[1] Journal of Cutaneous and Genito-urinary Diseases, vol. xiv., 1896, p. 89.

[2] *Ibid.*, vol. x., 1894, p. 1.

times accompanied by vesicular and bullous eruptions, fever, and severe constitutional disturbances which are followed by death. We have in such cases a clinical picture of a severe toxæmia, the nature of which, however, can only be surmised.

Intermittent fever, headache, and other general symptoms may accompany the localized forms of the disease, as shown in the following case:

Case II.—Lupus erythematosus of the face and scalp with general symptoms. The case was one of long duration but attended by acute exacerbations, during which the patient suffered with chills, fever, intense headache, pains in the bones, and from a swollen and painful condition of the face. These attacks have recurred each year for fifteen years, lasting several weeks. The patient, a woman aged seventy years, says her scalp was affected twenty years ago; the left side of the face was next involved; the right side for only a year. The vermilion border of the lower lip is slightly affected. Both forearms are the seat of an itching papular eruption, the skin in this location being much thickened. The scalp patches are markedly atrophied. On the face the atrophy is not so marked, but can be made out. She was seen during a febrile attack and it was noted that the face was much swollen, painful to touch, and the color a more vivid red. After the fever subsided, the pain and swelling of the face almost completely disappeared. The development of new patches was not observed during the acute febrile attack. Nothing in the general condition of the patient was detected which could be invoked to explain the skin affection.

Case III.—Lupus erythematosus secondary to tuberculosis of the skin. This case was presented before the New York Dermatological Society,[1] at which time several opinions were expressed as to the nature of the eruption. She would not consent to have a picture made, nor to the excision of a piece of skin for microscopic purposes. The patient was a woman fifty years old, a widow. She had been married twenty-five years, during which time she had had six children and one miscarriage; five of her children are living and well. Eleven years ago she had a paralytic stroke affecting the right side and followed by a loss of speech which persisted for two weeks. At the present time she has a symmetrical erythema of the cheeks and nose of a purplish-red color, with slight elevated and well-defined edges; on the right cheek there is considerable atrophy of the skin, while on the opposite side there are several retracted scars. On the right side also a subcutaneous nodule can be made out. The left ala nasi is partly destroyed from an old ulceration. There is considerable induration underneath the erythematous lesions, but no scaling or separate nodule suggesting lupus vulgaris. Her right ring finger is swollen from involvement of one of the phalangeal bones.

We were at first inclined to think that the woman had had syphilis, upon which a lupus erythematosus had become engrafted. Large doses of potassium iodide had failed to produce any effect upon the induration or the bone lesion. Lesions on the cheek had existed about eight years. After a thorough trial of the iodides the diagnosis of tuberculous gummata, which had healed leaving retracted scars and the present affection, an unusual type of lupus erythematosus secondary to skin tuberculosis suggested itself. It is difficult to impart to others the impression produced on one by the careful observation of a case of cutaneous disease which does not conform to the usual types. In this patient the long-continued redness and infiltration of the nose and cheeks, with atrophy, and absolutely none of the diagnostic features of lupus vulgaris, would almost force one to the conclusion that the active process was a lupus erythematosus.

At the same meeting of the society[1] Dr. Jackson presented a young man who had previously had numerous patches of lupus erythematosus of the face, which had disappeared after the excision of strumous lymph nodes from the neck. Two years after he was found to have lupus vulgaris. The history of the case seemed to show clearly the intimate connection between the tuberculous lymph nodes in the neck and the eruption on the face, the spontaneous disappearance of which after removal of the tuberculous foci would speak against its having been a primary lupus vulgaris.

Bronson[2] has reported a case of erythematous, scaly and pustular eruption, probably an atypical lupus erythematosus, in a woman with tuberculous lymph nodes in the neck, which disappeared after the nodes were removed. The eruption recurred with each recrudescence of the focus in the neck.

These cases are exceedingly suggestive, if they do not furnish the actual proof that an extra-cutaneous tuberculous focus may be the source of toxins capable of producing lupus erythematosus or closely allied eruptions. In addition to the cases briefly referred to in this paper, we have notes of three others in which the patients were affected with general tuberculosis. A report of one of them with the autopsy findings can be found in the *Journal of Cutaneous and Genito-urinary Diseases*, vol. xvii., 1899, p. 113.

The frequent association of lupus erythematosus and tuberculosis, together with the occasional outbreak of the former disease as a generalized eruption with severe constitutional symptoms, favors the view of those who connect the two processes by means of the toxin of the bacilli. The characteristic atrophy of the connective tissue may be brought about by the necrotizing principle of the germs, which Dr. de Schweinitz has shown to be a crystalline substance that is intensely active in minute quantities.

Should it ever be possible to prove this hypothesis, which has a certain amount of clinical evidence to support it, a satisfactory explanation would be afforded of those rapidly fatal cases of the disease which have been described by Kaposi, Hardaway, Besnier, and others.

The Pathology of Lupus Erythematosus.—By O. H. Holder, M.D. Two years ago, in a paper read before the Harvard Medical Society of the city of New York, and afterward published in the *Journal of Cutaneous and Genito-Urinary Diseases*, May, 1897, an attempt was made to bring the condition of lupus erythematosus into closer relation with the obstructive processes seen in the finer vessels, a point which was not of general observation and which seemed worthy of the most careful consideration. At that time but few sections were at our disposal, but through the efforts of Dr. Fordyce and myself, during the two years, tissue has been obtained which has afforded us sections which number slightly over one thousand. In regard to the treatment of this material, formalin two per cent., absolute alcohol, and saturated solution of bichloride of mercury were used as fixing agents, and the specimens were afterward embedded in paraffin and mounted serially. The paraffin and staining on the slide methods seemed especially applicable to our work, as we wished to retain as far as possible the contents of the vessels, and that the albumen fixative perfectly accomplished its object is demonstrated by the presence of the mononucleated leucocytes in the capillaries. Comparing these sections with the older ones embedded by the celloidin process, we cannot help feeling that this important factor of the disease is often lost, and it may account for the difference of

[1] Journal of Cutaneous and Genito-urinary Diseases, vol. xv., 1897, p. 133.

[1] *Ibid.*, vol. xv., 1897, p. 134.
[2] *Ibid.*, vol. xv., 1897, p. 225.

opinion recently expressed by writers. None of the killing fluids used by us seemed of especial value. After all of them the tissue cuts readily, for the epithelial layer is exceedingly thin and the scar-like atrophy differs entirely from sclerotic tissue.

Fig. 3.—Lupus Erythematosus: Face. Spencer objective ½ inch; Zeiss proj. ocular 2. Approximate magnification × 120. Stain, hæmatoxylon and eosin. From fully developed erythema. Very irregular dilatation of capillary. Granular masses to the left are normal red blood corpuscles. The peninsula in centre is completely surrounded by endothelium which shows the hyaline strip below to be within vessel. The two blood areas above connect over isthmus in next section. Slight development of plasmoma to the right. Finger and toe processes of the epithelium obliterated.

When serial sections were made, hæmatoxylon and eosin or Congo red were used. The special stains used in the investigation of the connective-tissue changes will be taken up in detail later in this paper. All the specimens were from the discrete class of the disease, only one case of the disseminate type appearing at the clinics, this patient refusing to submit to the removal of tissue. The most acute of our specimens was the telangiectatic case reported by Dr. Fordyce in the *Journal of Cutaneous and Genito-Urinary Diseases*, March, 1899.

In order that a comprehensive view of the process might be obtained, tissue was excised with the Keyes circular punch from the three clearly defined clinical areas, the periphery of the lesion, the raised erythema, and the atrophic centre. The microscopical appearances in these areas differ widely, and, in a full description of the disease, it has been the custom to give a separate place to each; but as these differences are only a question of degree, such a scheme gives a wrong impression, and is hereby abandoned to take up the main pathological factors as they vary in going from the periphery toward the centre. These factors making up the histo-pathological complex are few, and may be divided into three groups: (*a*) The round-cell infiltration; (*b*) the peculiar degenerated condition of the connective tissue; (*c*) the secondary atrophy.

(*a*) The round-cell infiltration has for a long time been considered the most important phenomenon of the process, and is, as far as can be seen, the primary departure from the normal. It is best studied in young lesions, although tissue taken from 2 to 4 mm. outside an old erythema answers as well. In both of these positions, in which it is fair to presume that the process is in the earliest stage of development, the infiltration is distinctly perivascular, and is well described by Unna under the name of plasmomatic. These infiltrated areas consist of open capillaries, which are surrounded by very loosely packed leucocytes. The capillaries here are enormously dilated and of irregular outline, but show no sign of endothelial proliferation (Fig. 3). Those affected are confined to the network of the upper and middle corium, and in the early stages there is no tendency to involve the capillaries of the hair follicles or glands. This error has crept into the literature of the subject by the examination of mature lesions.

The round cell consists here of a brightly staining nucleus surrounded by a clear homogeneous body with a very slightly differentiated cell wall. I have been unable to bring out any body reticulum of these cells with acid fuchsin, eosin, or other plasma stains, but attach little importance to the fact beyond inferring that they are well placed as far as their food supply goes. In this connection our observations are also in accord with those of Unna that there is no granular or fatty degeneration. When we move toward the atrophy, the leucocytes become more and more closely packed, making it even more difficult to make out the cell walls. The dilated capillary in their centre becomes compressed and is often difficult to trace. New and deeper areas are involved and now extend to the follicles and glands, and down into the fat bodies where the typical plasmomatic appearance of the earlier affected vessels is beautifully paralleled.

It is not unusual now to see, in those cases which do not have a tendency to sink in, a great mass of leucocytes filling the corium from the level of the sweat coil to the epidermis, or running horizontally for great distances. These larger areas are apparently unconnected with any vessel and are sharply circumscribed. Such a one is shown in the photograph (Fig. 4) and tallies well with one of the recent descriptions of the French. There is, however, no evidence of a tuberculous nature in this process, for this particular photograph was taken from a lupus erythematosus of the cheek in an English coachman, who insisted on the fact that it came four years before from a frost-bite. The erythema was about the size of a silver dollar and showed no tendency at all to atrophy or spread.

Fig. 4.—Lupus Erythematosus: Face (Cheek). Spencer objective 1 inch; Zeiss proj. ocular 4. Approximate magnification × 100. Stain, hæmatoxylon and eosin. Height of erythema. Shows extensive focus of infiltration in a case which had no tendency to atrophy. Small plug in opening of sweat duct. This is the circumscribed area described by the French.

When we get to the atrophy, the leucocytes are again beginning to lessen in number, and here occupy the dilated lymph space last involved, namely, between

the muscle and nerve fibres. Before leaving this subject one point must be mentioned that has the most important bearing on the pathology—that is, our knowledge of the life history of these cells. How much is really known of their origin, how long do they exist, and what is their ultimate fate? Of the first and last of these questions, the answer is pretty clear. We are almost sure that they come from the blood current. Such is the general opinion of dermatologists, and this point may be considered closed, for they can be demonstrated lying free in the capillaries. It is also the opinion that they undergo some form of degeneration and disintegrate, and as they have mostly disappeared in atrophic portions, this point, too, may be considered justly terminated. How long these cells live is an absolutely unknown quantity, for there are no means at our disposal of estimating any such question of time. It may be weeks or months. In our opinion past writers have put the probable time much too short. They give in their works the impression that the cells are rapidly dying and being replaced, and we feel that there is no ground for such an idea. The fatty and granular degeneration is an error of observation when spoken of as characteristic

Large number of leucocytes within the atrophied Malpighian layer.

of the process, and as to the compressed look of the cells in the older lesions, this is probably due to contraction of the connective tissue, and is of no special significance as regards the vitality of the cells.

(*b*) In passing to the changes in the connective tissue, we come to the consideration of a less recognized, though equally important process of the disease. Indeed, were it necessary to make a diagnosis from sections, it is here that the nearest approach to a pathognomonic sign could be found. In the youngest lesions, this change is slight but always present, and is confined to small areas in the upper corium, which are irregularly surrounded by the typical plasmomatic capillaries. The collagenous tissue in them looks grayish and swollen, suggesting the appearance of a coagulation necrosis, and with the usual dyes does not stain (Fig. 5). As Unna points out, his acid orcein solution gives a sharp, dark-brown color, but his inference that this degeneration contains elastin is not proved. The tinctorial characteristic of this substance is decidedly against Unna's statement, for although it takes up acid orcein (Fig. 6), it does not react to the other recognized stains for elastic fibres. The three mordanted hæmatoxylon methods, namely, Mal-

lory's tungstic acid-hæmatoxylon, Herxheimer's iron process, and the iron-alum method of Heidenhain, give beautiful stains here for the elastic fibres, which are well preserved even to the end of the process, but leave this substance absolutely uncolored. Van Gieson's stain gives an opaque yellow. With the plasma stains, eosin, erythrosin, orange G and Congo red, there is a marked color, but the peculiar opacity is still retained and brings it into sharp contrast with the normal collagenous tissue below. When the old lesions are examined to see the ultimate fate of this

tissue, we see it forced up toward the surface and slowly disappearing. Its height of development seems to be when the height of the erythema is reached, and its formation is in some way connected with the plas-

momata. Of these two important processes, it is impossible to say surely which is the cause of the other, but we are inclined to put the vascular disturbance as

Fig. 8.—Lupus Erythematosus: Scalp. Spencer objective ¼ inch; Zeiss proj. ocular 2. Approximate magnification × 180. Stain, hæmatoxylon. From atrophied portion. Granular obstruction in fine vessel.

the primary one, because a similar change can be found in rosacea. In no other disease have we ever had any success, although it is our custom to stain almost every specimen that we get with this solution. No other stain can compare with acid orcein when it is the object to bring out the elastic fibre, but we have found thionin superior to Unna's polychrome methylene blue for its counter-chromatin stain. It gives a much sharper color, and is recommended for lupus erythematosus.

Besides this cloudy appearance of the collagenous tissue, there are many other changes in the connective tissue, though none belong to the early lesion. In le-

sions fully developed, a clear homogeneous band runs along below the lowest layer of the epidermis, giving the appearance of a much-thickened basement membrane. Above it, the epidermis is always thin, and through it vessels pass and carry the leucocytes into the prickle layer. A similar metamorphosis seems to be present in the walls of the vessels, and possibly to it may be connected the casts found in the sweat glands and in the dilated capillaries of our telangiectatic case. This substance is not stained by acid orcein, and must not be confused with the change in the collagenous tissue.

(*c*) Included in the secondary atrophy must be grouped not only all the epithelial changes, but many of those of the cells of the connective tissue and its differentiation. While there may be a slight degree of thinning of the prickle layer in early lesions, I should say that, as a rule, all the epithelial constituents are close enough to it to be called normal. It is extremely difficult to be sure in this regard, for the two places where these lesions are most common, *i.e.*, on the cheek and scalp, differ anatomically from each other in a marked degree. The method of excising small pieces is faulty, because it gives us no healthy skin for comparison with the diseased.

The changes in old lesions have been fully described, and were it not that many curious develop-

ments have appeared in our sections, we should have nothing to add. Of these the most interesting are the sweat glands. More or less dilatation of the coil seems to be an extremely common result as soon as the infiltration has reached the adjacent capillaries. It must not be considered a general feature, for while one coil is much dilated, the next may be little or not at all. In those we followed out, there were both a large plug (Fig. 7) in the orifice and a marked lymphangiectasis, with infiltration in the upper part of the duct. As there is no reason to suppose that the normal sweat is under pressure, this transference of the lymph pressure to the fluid in the cavity of the gland may account for the dilatation. The intra-canalicular growth of the duct shown in the photograph was rare, being confined to one case from the face. Both hair follicles and sebaceous glands in these sections present much the appearance generally described, the atrophy in both being always accompanied by the presence of the infiltration among the epithelial cells. The muscle and nerves, as have been said, are attacked only after a long time.

Turning our attention to the condition of the vascular system, we see the most interesting of all the pathological changes. It was stated early in the paper that the obstructions in the vessels had been formerly noted (Figs. 8 and 9), and that our work of the last two years had been carried on with the express purpose of verifying the question of their existence. The literature on this point is extremely scanty and does not do justice to its importance.

An obstructive inflammatory process in the larger vessels is described by Leloir, under the name of endoangiotitis obliterans, but no great stress is laid on it. The existence of this process is denied by Unna, whose descriptions and observations are always most careful. Recently two large meetings of dermatologists have been held in which the discussion of this disease was made a principal feature. In that of the American Dermatological Association, held in Princeton June, 1898, Dr. Robinson, of New York, the reader of the paper on etiology and pathology, absolutely denied that there was any thrombosis, but later Professor Boeck, of Christiania, at the meeting of the section in dermatology of the British Medical Association, held in Edinburgh, Scotland, July, 1898, said he had seen the thrombosis as described. As far as our own observations go, we can say that we have seen markedly obstructed vessels, as described by Leloir, but as these vessels are much atrophied, the identification of an endarteritis is impossible. In most cases the cells, which occupy the old calibre of the vessel, seem to be quite similar to those familiar to pathologists in organization of thrombi from the vessel wall (Fig. 10). Never is there seen anything which resembles the endarteritis of syphilis, and hence Leloir's nomenclature is confusing. Emphasis must be laid on the fact that this involvement of the large vessels belongs to the process only after a long time, for it is never seen at the periphery of the lesion, and cannot throw light on the etiology of the disease.

Of those changes of the early lesion, two are ever present, the mantling infiltration of the capillaries and the dilatation of their calibre. On the strength of this infiltration alone, the disease has been classed as an inflammation of the skin by Kaposi and others. Much better would it be to call it a disease in which the vascular condition of an acute inflammation is reached and persistently maintained. That these two conditions can be other than evidence of an abnormally high pressure is impossible, and it is clear that they must afford the main basis for theoretical speculation on the pathology.

Most important in the first place would be the relation of this condition to general pathology. Nothing, however, has ever been obtained along this line, and a pathology has been devised for the disease more or less based on the peculiar anatomy of the skin. Among those to whom I have shown sections was Prof. E. K. Dunham, who said that the only place which he had seen similar vascular changes was in certain specimens of interstitial nephritis, but that he was not familiar enough with the various inflammations of the skin to give an opinion. It is true that the skin has much in it that has a separate pathology, and there is nothing in it more specialized than the vascular system when we consider it over the flush area, one of the favorite sites of lupus erythematosus. Yet I cannot help feeling that some time light may be thrown on this subject by the comparative study of general pathology. Professor Dunham's observation is particularly valuable in that an increase of pressure is the chief feature of these two processes; and the suggestion is not out of place that both lupus erythematosus and rosacea are worthy of the most careful comparison with the various conditions embraced under the name of interstitial inflammation.

If we admit that an abnormally high pressure exists in these plasmomata, we are able then to work out to a certain degree the cause. By following along the course of the vessels, we are able to tell whether obstructions from within exist. While the short downward extension into the fat bodies gives a clear answer to this question in the affirmative, the extremely small lateral extent of our sections prevent the following out of most of the plasmomata at the periphery. In a few cases I have reached the area of densely packed capillaries and lymphatics, but in following out others would say that this plasmomatic condition never leaves the vessel in going toward the centre of the lesion. This unbroken involvement of the upper corium, and in fact all evidence that the microscope can afford, exclude all ideas of an inflammation from a local septic cause. It is extremely rare to find red blood corpuscles in these dilated capillaries, though they must be free from any tendency to contract and drive them out during fixation. Free leucocytes are extremely common, and help to prove that owing to high pressure and slowed stream the marginal currents are alone deflected into the lesion, and the segregation of the white blood corpuscles is the result.

The choking of the capillaries and lymph spaces, as above described, is the main vascular condition in the erythema, and to it may be attributed the mechanism by which the pressure is maintained in the plasmomata, and the lesions spread. It is hardly correct to speak of it as a capillary thrombosis, for all evidence of clotting, beyond the massing of the leucocytes, is absent. No fibrin, even in the most densely packed areas, can be demonstrated by Weigert's stain, but this has nothing to do with the obstructed action of the position of the cells, and is a sign only of the extreme chronicity of the process.

The etiology of lupus erythematosus throws almost no light on the pathology, two conditions only appearing to hold antecedent relations with the disease. One of these, a local injury of the corium, includes cases which have been reported to have followed frost-bites and tattooing. The other is tuberculosis. In the last two years three cases in the first group have come under our observation, two of frost-bite, and a third rather vague case which followed scarification for rosacea. Of the second group, we have one in which there was no uncertainty of coexisting tuberculosis. This was the telangiectatic case which came to autopsy. Five others complete our list. In these no special examination of the lungs was recorded, but granting them all to be tuberculous, our list shows no such percentage as that of the French school. So uniformly do their records run that it is not out of place to bring up a possible solution of the actions of toxin. If anything is absolutely known about lupus erythematosus, it is that Koch's bacillus is not present in its lesion, and the disease is not true tuberculosis of the skin. Were it possible to establish the chain by which remote foci can act through the blood current, the long record of cases in France becomes of great interest and importance. The link in this chain is commonly ascribed to the stimulation or paralysis of the vasomotor centres, or to the direct action of the soluble poison on the walls of the vessels. Both these ideas are unanswerable, for pathological anatomy can neither indorse nor refute them, and it is not unlikely that they may always remain to explain in a vague way the existence of many of the erythemata and general tuberculides. Lupus erythematosus is too local a process to be attributed to a chemical disturbance of the vessel wall, for all the vessels of the skin must be subjected simultaneously to an identical action, and they show no sign of it. To the early observation of the skin, the vasomotor theory of the physiologists and the allied theories of pathology owe in part their ex-

istence. No one can dispute the care with which these observations have been made, nor the clearness of the experiments and their results. It is only the inferences that are too hasty. The limited space of this paper does not permit a lengthy discussion of these theories, and so in a few words I shall try to point out what seems to be one of the gravest errors in their application to the skin. An important, and perhaps the most important specialization of the skin in warm-blood animals is the control of heat by the dermic blood supply. In giving that control to the differentiated arterial walls, as the modern vasomotor theory does, not only is the seat of action removed from the upper corium, but the main muscles of their skin are completely neglected. In the well-known experiments on the rabbit's ear, dilation follows the cutting of the sympathetic nerve. The question is, Does this nerve go to the vessel walls or to the unstriped musculature of the corium; and is the secondary contraction the result of a return of the arterial tone or a filling of the lymph spaces, and the closing of the walls of the capillary by the equalization of lymph and blood pressure? Not the slightest evidence has ever been brought forward that the normal capillary wall in the skin is not at rest, and the pressure without equal to that within. The known movements of lymph and venous blood are an absolute proof of this statement. This all-important question of the lymph pressure is always lightly touched on in physiologies, because it affords almost no means for experimentation nor data for abstruse mathematical calculations.

Anatomical findings show many muscles running diagonally from the deep corium toward the surface, and as these are attached indirectly to the epithelial layer through the attachments of the connective tissue, either they must have no normal traction or the skin must be pulled down on the lymph space and capillaries. The laws governing the movement of fluid in the body are those which physics has proved in regard to confined fluids and should be so applied, the capillary wall being really submerged whether it is patent or not. We place, then, this lymph pressure under the control of these muscles, though the entire connective tissue is concerned in its maintenance. It is clear that any interference with their contraction must mean the loss of lymph pressure. Following out the possible variations, it is clearly seen that relaxation of either the muscles or the connective tissue would cause dilated lymph spaces and diapedesis, and although there might be a paralysis of the muscle from a toxæmia affecting the vasomotor centre, it is more likely that it is the connective tissue which is concerned and which we have shown to be very early involved in lupus erythematosus. If the swelling of the collagenous tissue means loss of function, it is possible that the infiltration is secondary to it. I admit that our sections by no means exclude this solution, and this unknown chemical change may be the result of toxæmia and hence tuberculosis.

In summing up the results of our work there is little to be said. Everything that is seen in the microscope points conclusively to the fact that lupus erythematosus is a disease in which the blood supply is interfered with. The normal capillary pressure is raised, but the cause is open to further investigation. Of the two phenomena that are characteristic of the early lesion, we are inclined to place the infiltration secondary to a capillary obstruction in the height of the erythema, but we allow at the same time that it may be the effect and not cause of the connective-tissue change. As this still requires further work, we again take the opportunity to recommend to both pathologist and dermatologist the use of Unna's acid orcein in lupus erythematosus.

ENDOCARDIAL MURMURS OF ORGANIC ORIGIN, LOCALIZED IN THE PULMONARY AREA OF THE HEART.[1]

By JOHN WINTERS BRANNAN, M.D.,
NEW YORK.

At the last meeting of the society, a patient was presented with full clinical history and well-marked physical signs of cardiac disease, and yet the difficulties in the case were so great that most of the gentlemen present hesitated to venture a diagnosis without further observation and study of the case. I have brought the patient again to-night, in order that the members of the society may have another opportunity for examination.

The case, in brief, is as follows: The patient, Arthur Jasper, a well-nourished young negro aged sixteen years, was born a healthy baby, with no evidence of congenital defect of any kind. He remained well until the age of five years, when he had an attack of acute articular rheumatism involving also the heart. At seven years of age he had another attack, accompanied with cardiac disturbance. Since that time he had had more or less palpitation and dyspnœa, but has been able to pursue his occupation, that of a peddler. The illness from which he has recently recovered began about March 1, 1900, with cough and pain in the side, fever, sore throat, and headache. The ankles and knees became swollen, painful, and tender, and he was unable to walk. The cardiac symptoms mentioned above became more marked and at times he could not breathe in the recumbent position. On March 21st, he was brought to Bellevue Hospital.

On entrance, the patient's temperature was 104° F., the pulse 100, and respiration 28 to the minute. He had frequent cough with slight muco-purulent expectoration and some dyspnœa. The lungs were normal except for sonorous and sibilant râles throughout both sides of the chest. On examination of the heart, the apex-beat was difficult to locate, but could be seen, wave-like in character, with greatest distinctness in the fifth space in the nipple line. The cardiac impulse was stronger over the base than at the apex. Over the whole præcordium there was a systolic thrill with maximum intensity in the second left intercostal space. On percussion, the left border of the heart appeared to be three inches from the median line of the sternum, the upper border at the third rib, and the right border three-quarters of an inch beyond the right edge of the sternum. A long, loud, rough, systolic murmur was heard over the whole cardiac area, with maximum intensity in the second left space close to the sternum. The murmur was also heard over the left side of the chest in front and behind, and was apparently transmitted into the carotid and subclavian arteries. The second aortic sound was very faint, the second pulmonic accentuated. The action of the heart was rapid and irregular. There was no pulsation in the epigastrium nor in the vessels of the neck. The mucous membranes were of a healthy red color, and the sphygmographic tracings were alike in both radial arteries, not varying much from the normal.

The patient rapidly improved with rest in bed and treatment with the salicylates, and at the end of ten days he was up and about the ward doing light work. The physical signs in the chest remained as before, except that the lungs were free from râles and the heart's action had become slow and regular.

When he was presented at our meeting, five weeks ago, there was no cyanosis, no clubbing of the finger ends, no embarrassment of breathing or of the circulation, and nothing to suggest disease of the right side of the heart except the murmur and thrill in the pulmonary area and the cardiac enlargement to the right of the

[1] Read at a meeting of the Practitioners' Society, May 11, 1900.

sternum. The murmur was heard with equal intensity throughout the respiratory act. The thrill was then present, but has now disappeared.

Before I had been able to make even a probable diagnosis of this case, a second patient entered the hospital with physical signs which were almost identical with those in the first patient. The history of the case is as follows: The patient is a young man twenty-three years of age, a stoker by occupation. He has been a hard drinker, but has had no illness except the diseases of childhood. His present illness began about February 1st, with pain and tenderness in the wrists and ankles, and gradually involved the knees, right shoulder, and hips. The pain was accompanied with some swelling of the joints. There has also been at times palpitation of the heart, but no dyspnœa or cough. On April 5th, when the patient entered the hospital, the temperature was 102.2° F., the pulse 100, and the respiration 24 to the minute. Both knees were painful and tender and the left knee was red and swollen. There was also some stiffness of the left hip. The heart presented the following conditions: The apex beat was in the fourth space, distinctly seen and felt in the nipple line four inches from the middle of the sternum. The beat was forcible, not diffuse nor wavelike. The right border on auscultatory percussion was one-quarter inch to the right of the sternum, the upper border was at the third rib, the left border five inches from the median line. In the second left intercostal space close to the sternum was felt a systolic thrill. In this same region was heard a long systolic murmur, not transmitted in any direction. The murmur was somewhat inconstant. The valvular sounds elsewhere were normal. On the 7th of April it is noted in the records that the joints were much improved and that a distinct impulse was to be seen in the second left space. Three days later the thrill was no longer to be felt, and when the patient left the hospital on the 17th of April the murmur was not to be heard. I had hoped to present the patient to-night, but unfortunately he has left the city.

Since our last meeting I have given much thought and study to the subject of systolic murmurs in the pulmonary area, and have made such search of the literature as time would permit. The patient Jasper has also been kept under constant observation. The problem presented by this case may be stated as follows: Does the murmur originate in the pulmonary artery itself either as a result of structural change in the vessel or its valves, or as a result of pressure from without, or is it generated at the aortic or mitral orifice and conveyed thence in some manner to the pulmonary area?

Acquired affections of the pulmonary artery are extremely rare, whereas congenital malformations are not uncommon but are seldom observed except in infancy or early childhood. In the Transactions of the London Pathological Society, from its foundation down to the present year, I have found but two cases of acquired endocarditis of the right side of the heart. In one of the cases there was also a congenital defect of the interventricular septum, but the endocarditis was apparently of recent origin. The mitral, pulmonary, and tricuspid valves were all affected. In the second case the patient was apparently healthy at birth, though there is no note to that effect. The symptoms dated from an attack of scarlet fever in early childhood. The physical signs were indicative of pulmonary obstruction and regurgitation and of tricuspid insufficiency. Death occurred at the age of eighteen years, and on autopsy there was extensive disease of the pulmonary and tricuspid valves. There was no congenital defect, and the left side of the heart was normal with the exception of two or three small warty growths on the mitral valve. There are many cases of congenital malformations reported, and in all, when any clinical notes are given, there is a history of cyanosis or of dyspnœa or of more or less embarrassment of the circulation. A search of the transactions of the New York and Philadelphia Pathological Societies gives similar results. In our case, as we have seen, there was no cyanosis nor any sign of circulatory disturbance until the attack of rheumatism at the age of five years. I think, then, we are fairly justified in excluding congenital disease, and in believing that acquired disease of the pulmonary artery is in the highest degree improbable. Pressure upon its walls may cause systolic murmurs in the pulmonary artery. The pressure may be produced by aneurisms of the aorta, or by enlarged bronchial glands, or by tumors in the mediastinum or in the lungs. In the case of Jasper there are none of the usual local signs of an aneurism, and its existence is rendered improbable by the similarity of the pulse tracings in the two radial arteries. It is of course possible that there may be pressure from a gland or by a growth, but I do not think it likely in this instance. Systolic murmurs heard in the pulmonary area are believed by Quincke and by Broadbent to be sometimes due to incomplete covering of the conus arteriosus by the overlapping left lung, so that a part of the conus or the pulmonary artery itself comes into contact with the chest wall, and during systole is more or less flattened against the chest wall. An eddy is thus formed in the current of blood rushing into the pulmonary artery which gives rise to a murmur. Quincke states that in these cases the pulsation of the pulmonary artery can be seen and felt in the second left interspace. During a full inspiration the murmur disappears, as a cushion of lung is then brought over the conus arteriosus between it and the chest wall. Bramwell, however, thinks it doubtful whether the heart does or can compress the pulmonary artery in the manner which Quincke has supposed, as the "conus arteriosus descends to the plane of the base during the ventricular systole; and the length of the ventricle does not alter during the contraction of the heart." On the other hand, he reports two cases under his observation in which the left lung was retracted and systolic murmurs were heard in the second left interspace. In these cases he concluded that the murmur was exocardial and produced by the contact of the pulmonary artery, or rather the roughened portion of the pericardium which covers the root of the pulmonary artery, with the anterior wall of the chest. In both cases the retraction of the lung was due to pleurisy, and there was reason to suppose that the outer portion of the pericardium was roughened by a deposit of lymph. Bramwell noted the peculiar loudness, roughness, and localized character—not propagated in any direction—of the murmur in his two cases. I have never to my knowledge met with an instance of the murmur with the characteristics described by Quincke and Broadbent. The explanation offered by them can hardly apply to our case, for, as we have seen, the murmur is not at all affected by the act of respiration.

Turning now to the left side of the heart, let us consider the aortic and mitral valves as possible points of origin for the murmur. An aortic obstructive murmur is sometimes heard to the left of the sternum with greater distinctness than to the right, but never, I think, is the difference so great as in this case. Nor is the murmur in our patient really transmitted into the carotid arteries, although it is so stated in the notes of the case. On careful examination I find that the sound is simply conveyed up the left side of the neck through the bones and tissues just as it is carried everywhere throughout the left side of the chest. On the right side of the neck, and especially over the carotid artery, the murmur is heard very faintly if at

all. The pulse also does not show the tracing characteristic of aortic obstructive disease.

Having eliminated all other sources for the murmur, the mitral valve alone remains. Many writers have noted that the murmur of mitral regurgitation is occasionally heard in the pulmonary area, and various explanations have been offered for the fact. Naunyn was among the first to make this observation, and his theory of the causation of the murmur has been accepted by Balfour and other authorities. Naunyn holds that the murmur is conducted to the second left interspace through the dilated appendix of the left auricle. Normally the left auricle is almost completely hidden by the right side of the heart and the root of the pulmonary artery. But in disease of the mitral valve with dilatation of the auricle, the auricular appendix winds around the pulmonary artery and lies in front of it, in contact with the chest wall. In a case of mitral insufficiency, therefore, the reflux current of blood flows into the auricle, and as the appendix communicates freely with the auricular chamber we can readily see how the sound should be conducted to the second intercostal space better than toward the apex. Naunyn's murmur, however, is not heard with maximum intensity at the edge of the sternum, but at a considerable distance from it, about one and one-half or two inches to the left, or at the point which corresponds with the situation of the auricular appendix in these cases. In our case, on the other hand, although the murmur is heard very loudly at this point, the place of maximum intensity is without question close to the left border of the sternum. This situation is just over the mitral valve, and I have finally come to the conclusion that the murmur in this case is due to regurgitation through the mitral orifice and that it is transmitted directly upward from the place of its production. Sansom, in discussing the murmur of mitral regurgitation, states that in rare cases it may be audible only at the second and third left costal cartilages and the neighboring interspaces. He believes that in these exceptional cases it is due to the morbid material about the mitral valve being a good conductor of the vibrations, which become sonorous, to the so-called pulmonary area. In one case under his observation, he found on autopsy that a calcareous thickening about the mitral orifice, involving the cords and curtains in this position, was so extensive as to encroach upon the conus directly below the aortic valves, distinctly narrowing the lumen of the aortic orifice in this situation, and he thought that this might very probably be the cause of the systolic murmur heard in the position mentioned. Balfour, also, lays stress upon "the natural tendency of murmurs to be propagated to the surface through the organ in which they are produced (in this case by the impingement of regurgitant fluid waves upon the tense wall of the left auricle), provided the conditions are suitable." In another place he asserts that the slightest dilatation of the right ventricle pushes the left apex backward into the thoracic cavity and away from the chest wall. In our case the right ventricle is not dilated at present, whatever it may have been when the patient was in the hospital. It is, however, a fact that the apex beat has never been felt very strongly in the fifth space. At the time of my last examination, one week ago, I made the following notes: "Systolic impulse strong over the fourth left costal cartilage and in spaces above and below, more marked than over apex. Murmur heard with greatest distinctness in second left space close to sternum and carried loudly directly to left for an inch or two, also diagonally upward to the left with steadily diminishing intensity, but nevertheless more distinct under the clavicle than at apex. No second sound to be distinguished at the base over either aortic or pulmonic orifice, but well marked at apex." It would seem, then, that we have here the conditions necessary for the transmission of the murmur from the mitral valve directly to the surface above, the base of the heart being apparently in close apposition to the chest wall. The murmur is also conveyed strongly to the left by the reflux blood current through the auricle into the left auricular appendix, in the manner described by Naunyn. But the essential feature of the case, if I comprehend it rightly, is the conduction of a mitral regurgitant murmur directly to the chest wall above, to the so-called pulmonary area.

I have not discussed the mechanism of the functional murmurs heard in the pulmonic area nor the diastolic murmurs of organic origin localized in this region, as they did not seem pertinent to the subject under consideration and would have added unnecessarily to the length of the paper.

CONVULSIONS.[1]

By CLARENCE KING, M.D.,

MACHIAS, N. Y.

So accustomed are we to hearing certain symptoms spoken of as the names of disease, that it is difficult for us to realize, or for the public to comprehend, that we have not made a diagnosis when we assign one of these as a cause of sickness. We recognize as a disease a condition attended by definite pathological changes of a nearly uniform nature and accompanied during life by a certain line of symptoms. Hence every disease is made up of several symptoms; and, likewise, each one of these symptoms may belong to several diseases. So it is well for us, occasionally, to study these general symptoms, and to-day I shall consider convulsions and point out some of the diseases which they may accompany.

A convulsion may be defined as a sudden explosion of nerve force which is manifested by involuntary tonic or clonic contractions of the general muscular system or a large part thereof, usually with loss of consciousness and insensibility, and tending to irregular recurrences. Convulsions are very common, and every one who has seen much sickness or mingled much with the world has seen them in some form. Practically all convulsions partake of the same general characteristics, the only difference being in degree. Thus, general eclampsia or a fully developed case of grand mal may be taken as the type of the more violent forms, while localized convulsions or Jacksonian epilepsy represent the milder forms. Spasms, which involve a single muscle or a very small group of muscles, like wry-neck, athetosis, or writer's cramp, are of the same general order, yet should not be classed as convulsions on account of their strictly localized and very mild nature, and unimportance as regards life or future health. Likewise chorea, paralysis agitans, and the tremor which is common to advanced age do not come within the scope of our definition because of their continuous and protracted character, and the want of that sudden "motor discharge" which forms one of the leading features of a convulsion.

Clinically, we may divide convulsions into two classes—those which occur in adult life and those which occur in infancy and childhood. In adults convulsions are most often produced by epilepsy, hysteria, or poisoning by some substance introduced from without or developed within the body. Many organic diseases of the brain, as tumor, hemorrhage, inflammation of the substance of the brain or its coverings, and traumatic injuries, especially those which produce

[1] Read before the Thomas J. King Medical Club, November 23, 1899.

irritation or pressure on the motor centres, are frequent causes. Cerebral syphilis, tetanus, the flushing out of a pleuritic cavity, and sudden disturbances of the circulation, as sometimes happens in syncope or in fatty degeneration of the heart, are also well-recognized causes. Reflex irritation from other organs, as the uterus, the nose, or the eyes, has been considered by many a potent factor in producing convulsions in some persons; but its influence in adults is denied by others. Malingering is an occasional cause among prisoners accused of crime or rogues seeking to profit by the excitement which a fit in a public place produces. And, lastly, it occasionally happens in the course of an acute rheumatic or malarial attack or certain other diseases, but here, as in tetanus, it is a question if it is not due to the same poison which is responsible for the primary illness, and hence should not be mentioned as a separate cause but included in the class due to poisoning.

Case I.—Looking back at least twenty-five years I well remember the first case of general convulsions I ever saw. It was the case of a man aged about twenty-five years, who was a patient at the county almshouse, and who had strayed away to a picnic in a neighboring grove. I heard his initial scream, and with the crowd hurried to the place where he lay. He was then in tonic spasms, his face turned to one side, his mouth and eyes drawn to the same side, his arms and legs extended. The muscles of his whole body were rigid so that respiration was nearly suspended, and as a consequence his face was cyanosed. Soon he slowly turned his face to the opposite side and clonic twitchings of the muscles of his face and eyelids began, which extended to the limbs and body. His respiration was irregular and froth came from his mouth, but it was not bloody. After a little the twitching of the muscles gradually subsided, and in about ten minutes he sat up and looked around in a dazed and bewildered manner. Soon after he got up and slowly made his way to the cottage some half-mile distant.

Here, then, was a typical case of epilepsy. How long it had lasted or what was its cause were alike unknown to me. It might have been idiopathic; that is, it might have occurred without assignable cause, and it is to this class of cases I would restrict the word epilepsy; or it might have been due to one of the other causes I have enumerated. Idiopathic epilepsy is perhaps most commonly due to heredity or the neurotic temperament, in which one form of nervous disease appears in one member of a family while other forms attack other members of the family. Sex and age are also important factors, the greater proportion of cases occurring in females under thirty years of age. So important is age as a predisposing factor that we can lay it down as a general rule to which there are few if any exceptions that "an epilepsy developing after the age of thirty-five is not idiopathic but is due to organic brain disease, the abuse of alcohol, reflex irritation, or other cause," which may be so obscure that we cannot discover it. Climate, season, race, and occupation may also have determining influences as tending to enfeeble the general stability of the nervous centres. But these are practically all the causes of idiopathic epilepsy, as now recognized, and undoubtedly true idiopathic epilepsy is rarer than generally believed. Every case of convulsions should be thoroughly investigated before being pronounced epilepsy of idiopathic origin, as such a diagnosis amounts to practically the same as an admission of ignorance.

Case II.—F. B——, aged about thirty years, suffered a fracture of the skull in the temporal region when only two or three years old. He was attended by a competent surgeon who removed several pieces of bone, and the wound healed nicely. Some years afterward he began having convulsions, which became so frequent that he would sometimes have six or eight a day for a week or more at a time. These convulsions differed in no way from those described in the first patient, and as a result of them he lost his mind entirely and also became partially deaf. Dr. Hammond, of New York, was consulted, but refused to make any operative interference on the ground that all was done for him at the time of the injury which it was possible to do, and that the point of irritation was probably inaccessible to the knife. The man remained in this way until his death some four or five years ago.

The convulsions in this case were evidently due to the injury, but whether the irritation was caused by a spiculum of bone which was overlooked at the time of the operation, or by inflammatory thickening of the dura, I was unable to ascertain, as an autopsy was denied me. I am, however, inclined to the latter view on account of the time which followed the injury before the convulsions began.

Injuries to the head causing concussion or contusion of the brain often give rise to convulsions, as in the following case:

Case III.—J. M——, aged thirty-two years, weight one hundred and ninety pounds, fell a distance of about twenty feet and struck on his head and shoulder. When I reached him he was sitting up supported by his companion, but did not know any one and could not speak. He had been unconscious for a short time, but would then look up when spoken to sharply. He was taken to his home and put to bed, and soon after had a convulsion which was followed that night and the next day by several others. He vomited several times, the first being clear blood, and had a sanious discharge from his right ear. Within a few days his right eyelid became badly ecchymosed. I do not recollect that there was any paralysis, but it was fully three weeks before he regained his consciousness sufficiently to be able to tell what was passing around him.

The next cause of convulsions which I shall consider is poisoning, and the list of toxic agents which may produce convulsions is quite large. Thus, we all know convulsions may be caused by alcohol, by lead, by strychnine, by arsenic, by mercury, and by urea. But there are many other poisonous substances which may cause convulsions which are not so well known but which we are liable to meet with at any time. Among these I may mention tobacco, aconite, veratrum viride, oxalic acid, and tartar emetic, as perhaps the most important. I have already mentioned malaria and rheumatism as sometimes causing convulsions, but it has also been demonstrated that the poison of other diseases, as pneumonia, typhoid fever, erysipelas, scarlet fever, and other grave diseases, especially if accompanied by excessive vital depression, high temperature, or marked toxæmia, may also produce them. As an instance of convulsions caused by poisoning by an unusual drug I will relate the following:

Case IV.—Mrs. A. B——, mother of two children, the younger two or three years old, kept an almanac at hand for ready consultation, and her peace of mind was regulated by it. She discovered one day that she had passed the time for her menses by at least three days, and after worrying all day took a drachm of oil of tansy at bed-time. Within half an hour she began having severe convulsions which were continued for at least an hour, during which time she must have had a dozen or fifteen. Most of these were severe and accompanied by frothing at the mouth. She finally recovered, but menstruation was not established until a week or ten days afterward.

The diagnosis of toxic convulsions must be made from the history of the case and those special features which are generally present, but often the character of the attack itself will greatly aid us. Thus, in uræmia

the convulsions are generally preceded by headache, by vomiting, and by œdema of the face and eyelids; there is seldom an initial scream; defecation and micturition do not occur, and tonic spasms are generally if not always absent. In addition to these an examination will show evidences of kidney disease, and the convulsions, if left to themselves, are apt to be repeated several times within an hour. Coma or unconsciousness supervenes after the first convulsion and defies all efforts to arouse the patient. In tetanus the spasms are developed gradually and first appear in the muscles of the lower jaw, are always tonic, and may last for many hours; consciousness is preserved, although obviously talking is impossible. Convulsions due to alcoholism are usually preceded by headache, vomiting, and excessive tremor, and are followed by mental derangement, often with hallucinations, especially of terror. The convulsions of strychnine poisoning take the form of opisthotonos and are excited by any noise or jar of the bed: clonic spasms of the neck and extremities are also present.

Hysterical convulsions form an important class and are frequently met with. Generally they occur in women of the child-bearing age, but are not confined exclusively to this period of life or even to this sex. Neurotic and emotional people are more prone to such attacks than others, and often some sudden mental impression, as joy, grief, or fear, can be given as the cause. The following case is typical, although more severe than many:

Case V.—G. L——, male, aged about twenty-eight years. I was called to see this patient as a consultant and arrived a short time before the attending physician. As the patient was then having convulsions I was hurried to his room, notwithstanding my expressed desire to await my colleague. I found the man on a bed with two men and half a dozen women and girls around him to hold him from throwing himself to the floor. His hands were firmly clinched and he was trying to free his arms from his attendants. As I entered he turned and looked at me and was quiet for a moment, but soon after arched his back in opisthotonos and while in that position threw himself violently to one side. Respiration was irregular and his face flushed from the exertion of his efforts, but not cyanosed. After the convulsion he appeared exhausted and relaxed all his muscles. His breathing was then rapid and shallow. They told me that before I arrived he had spoken and asked to be fanned; so they fanned him in the intervals between the convulsions, and he turned his face toward the person with the fan. Soon the rigidity of the arms returned and in about eight or ten minutes he had another convulsion. I watched him through one of these, and left the room without speaking. My diagnosis was made, but I refused to disclose it, and only told the anxious friends he would recover. When the doctor came I met him at the gate. He had seen the case before and thought it suggested strychnine poisoning; and later, upon learning that they had had a party at the house the night before at which the patient had eaten of ice-cream, advanced the idea of ptomain poisoning from the cream. I adhered to my original diagnosis, but said little to the family, only that it was my opinion he would get well, which of course he did in two or three days. Afterward I learned that he has since had similar attacks, and that in every case they followed excitement or disappointment, or other mental emotions.

Syncope occasionally produces partial or general convulsions which are known as cardiac epilepsy. The most prominent features, aside from the clonic spasms, are an intense coldness and pallor of the surface, which afterward becomes flushed, and a greatly diminished pulse rate. This never occurs unless there is fatty degeneration or other disease of the heart or blood-vessels which interferes with the proper nutrition of the brain; and hence happens most often in aged people.

Epilepsy and insanity are the diseases of all others which are simulated with the object of escaping punishment for crime or gaining sympathy. Ordinarily, the deception can be easily recognized, as the malingerer is apt to overdo the convulsive feature, while he omits or cannot simulate certain other symptoms which should accompany the convulsion. He seldom bites the tongue or falls so as to hurt himself. The corneal reflexes react normally, the pupils respond to light, the color of the face is rarely changed, and the prick of a sharp instrument produces evident pain. Yet the malingerer, by study and determination, may so school himself as to imitate nearly all the symptoms of epilepsy with some degree of perfection. Thus the celebrated case of Clegg, the prince of malingerers, may be mentioned. Clegg was known in street parlance as a "dummy-chucker," and his business was to travel the streets and have fits wherever he could get a crowd without danger of arrest, and then collect what alms was offered him and hurry away, while an accomplice picked pockets among the spectators. He was often arrested on various charges, but so well could he simulate epilepsy that he deceived many prison officials and physicians, and repeatedly escaped punishment and prison duty because of his supposed affliction. By practice he was able to imitate the clonic and tonic spasms perfectly, could control the action of the eye so as not to flinch when the cornea was touched with the finger, nor show any feeling when pins were thrust into his flesh. In an attack he fell heavily, often injuring himself, bit his tongue or injured his gums so that blood would be mixed with the froth which came from his mouth, and held his breath so as to produce a livid countenance. The fraud in his case was exposed by the facts that the nails were not livid, the rigidity of the muscles could be easily overcome, the sphincters were not relaxed, the fingers were not closed over the thumb, and there were no ecchymoses or extravasation to indicate recent injury.

In infants and children convulsions partake mostly of the same general features as in idiopathic epilepsy of adults, but the causes are not the same. In infants the nervous system is more highly developed in proportion to the other organs of the body than in adults, and hence they are more susceptible to disturbing impressions of these centres. Consequently, reflex irritations hold a higher place in the etiology of convulsions in them than they do in older people; and hysteria and intentional deceit cannot, of course, be considered.

Convulsions which occur during the first few weeks of life are generally caused by injuries received at birth. Obviously injuries to the brain are more apt to be received in instrumental deliveries, in breech presentations, and in cases of difficult labor in which the head has been subjected to compression for a long time. Just what these injuries are, or in what part of the brain they are located, it would be difficult to determine, but they are probably minute extravasations in various parts of the encephalon. We know that the infantile brain is poorly protected from pressure and that consequently it must be more tolerant than in the adult; otherwise it would be difficult to see how any child escapes death at birth.

The most frequent cause of infantile convulsions in reflex irritation from some disturbance of the gastro-intestinal tract. Thus, difficult dentition, indigestible food, intestinal parasites, a foreign body, or a loaded rectum may result in reflex action and produce them. We all know how common they are as a complication in the summer diarrhœas of young children, and that they generally cease when the bowel is flushed

its whole length. Other causes of irritation which may produce them are severe injuries or burns, phimosis, retention of urine, foreign bodies in the ear or nose, and in older children, according to Stevens, insufficiency of the ocular muscles.

The acute infectious diseases, as scarlet fever, measles, influenza, mumps, and typhoid, may be ushered in by convulsions, and it is asserted by some that high fever, whatever its cause, is sufficient to produce convulsions in children predisposed to them. The various toxic agents which produce convulsions in adults may also cause them in children. Rickets is a common cause among city infants but rare in the country, where rickets is seldom met with; and organic diseases of the brain, as tumor or meningitis, either tuberculous or not, may cause them. Acute cerebral and spinal palsy are occasional causes, and enlargement of the thymus gland is mentioned by Holt as a cause. And there are undoubtedly some cases which occur without assignable cause, unless we call them idiopathic epilepsy, but such cases are very uncommon. Other rare causes are also mentioned by authors, but we can disregard them as of little practical importance clinically, and their treatment differs in no way from those here mentioned.

The first indication to be met in a case of infantile convulsions, whatever their cause, is to relieve the muscular spasms and afterward to prevent their recurrence. To do this the child should be placed on a hard bed and left undisturbed as much as possible. Chloroform should be administered by inhalation and chloral by rectal injection. Cold should be applied to the head and heat to the body. It is hardly advisable to place the child in a hot bath on account of the disturbance it produces, but it is well to substitute a mustard pack for it. As soon as the immediate indications are met we should try to ascertain the cause of the convulsion, and if possible remove it. If due to intestinal irritation calomel should be given and an injection administered to empty the colon. Difficult dentition calls for lancing of the gums; high fever should be reduced by the cold bath or pack, and rickets treated with the usual remedies. In uræmic convulsions from kidney disease free sweating should be induced by the hot pack or vapor bath, and pilocarpine given combined with alcoholic stimulants to counteract its depressing effects. Saline cathartics should be given and hot poultices applied over the kidneys. As nephritis in children is almost always acute, stimulating diuretics should be avoided as tending to increase the congestion and inflammation of the kidneys; but in older children the free drinking of plain or feebly alkaline water should be encouraged to flush out the system without causing irritation to the diseased organs. Complications, such as pneumonia, pleurisy, endocarditis, and dropsy of serous cavities, should be watched for and treated, but most cases of uræmia in children result fatally.

In adults it is hardly proper to institute treatment before making a diagnosis as to the cause of the convulsions or at least deciding that they are not due to hysteria or fraud. Of course no particular harm would come from giving chloroform in these cases, but it is unnecessary, as they tend to spontaneous recovery and are not attended with danger to life. Uræmic convulsions and those due to strychnine or other drugs should have chloroform, and efforts should be made to eliminate the poison. Stimulating diuretics may be employed, as the Bright's disease of adults is usually chronic in nature from the outset, and hence there is little danger of increasing the inflammation of the kidneys. Atropine may be given hypodermically as a spinal depressant in strychnine poisoning and those other cases due to irritation of the spinal centres. Hysteria calls for nervines and offers a promising field for the use of hypnotism or suggestion. Idiopathic epilepsy rarely requires treatment during the stage of convulsions, but should have large doses of bromide of potassium, or better the combined bromides of sodium, potassium, and strontium, in the intervals, with arsenic added to prevent cutaneous symptoms, as they must be continued for a long time. Cardiac epilepsy calls for stimulants and the lowering of the head, and syphilitic convulsions require iodide of potassium.

Convulsions which can be traced to tumor or former injury of the head should usually be treated by operation. Trephining of the skull and the removal of thickened dura, spicula of bone, blood clots, or foreign growths have added lustre to modern surgery and cured many otherwise hopeless cases of convulsions. And in all cases of head injuries, even if apparently trivial, we should remember the great danger of convulsions as a late sequela.

Abortive Pneumonitis.—G. Pieraccini gives this name to the variety of pneumonia which lasts less than four days, its symptoms being otherwise the same as those of the usual fibrinous pneumonia. He reports a case. Jaccoud believes that these cases are not rare. The trouble may easily be overlooked because of its rapid course, and because it is often circumscribed. Leube saw two cases that lasted only one day. In the author's case, the finding of capsulated lanceolate diplococci in the sputum and in the blood, the injection of which in a guinea-pig caused its death from septicæmia, settled the diagnosis.—*Lo Sperimentale*, No. 2, 1900.

On Some Diagnostic Difficulties Associated with Dilatation of the Right Ventricle.—J. Stacey Wilson draws attention to the following signs of diagnostic value: (*a*) The character of the murmur: it is apt to be softer and more blowing in tricuspid regurgitation. (*b*) The nature of the vessel up which the murmur is conducted. The character of the pulsation is often a useful guide, being weaker and more fluttering in the veins, stronger and more even in the arteries. Also the pulsating parts of the vessel can often be felt to come to an end suddenly in the case of a vein. (*c*) The relative loudness of the murmur in the neck as compared with its loudness in the second right interspace may prove of service for diagnosis. In the case of the aorta, the loudness in the neck is always equal or nearly equal to its loudness over the second rib or interspace. In the case of murmur of tricuspid origin, if there is free regurgitation up the veins, the murmur may be as well conducted as the aortic, but as a rule it is not, and the conduction is not loud. (*d*) Another important sign is the relationship between the loudness of the first sound, and the murmur as heard in the arteries of the neck. If the first sound of the heart can be heard over the arteries of the neck, while the murmur is heard faintly or not at all, it is strong evidence against the murmur being of aortic origin.—*The Birmingham Medical Review*, June, 1900.

The Formation of a Circumscribed Intra-Dural Abscess at the Site of the Saccus Endolymphaticus.—Jobson Horne says that when pus is pent up in the labyrinth, it follows the line of least resistance in endeavoring to escape into the cranial cavity. One route is along the aqueductus vestibuli to a fissure on the posterior aspect of the petrous bone. Through this fissure the prolongation of the membranous labyrinth originally passes. This process, known as the saccus endolymphaticus, may remain in adult life sufficiently patent to allow the passage of pus. Horne

describes two cases of circumscribed abscesses at this point. Such abscesses he regards as within the reach of surgery, and this gives a practical bearing to the recognition of their possible occurrence in cases with symptoms pointing to intra-labyrinthine suppuration. As a point of interest, Horne states his belief that the pus is not contained within the saccus itself, but between the two layers of dura mater which originally contained the sac.—*Journal of Laryngology*, June, 1900.

Carbonic Acid Gas in Nasal Affection.—Joal highly indorses this agent and figures a special apparatus which renders its application easy. The most beneficial results have been attained in hyperæsthetic rhinitis. The ordinary carbonic siphon offers an easy means of applying the gas.—*Revue Hebdomadaire de Laryngologie, etc.*, May 12, 1900.

Persistent Adenoids in a Woman Aged Forty-Seven Years.—E. F. Potter reports the case, the symptoms in which were impaired hearing and difficulty of breathing through the nose. Examination showed the post-nasal space to be occupied by a considerable mass which obscured the upper half of the septum and extended across the vault from tube to tube. The growths were removed with forceps under an anæsthetic, and proved to be adenoid tissue which had undergone inflammatory changes. Nothing of a sarcomatous nature appeared under the microscope. The patient's hearing improved greatly within two weeks after the operation.—*Journal of Laryngology*, June, 1900.

Cystic Degeneration of Both Kidneys. — Fin Holmsen reports a case of this sort observed in an infant delivered at term by craniotomy. Both kidneys were found enlarged and filled with numerous small cysts separated by thick layers of connective tissue. No normal renal tissue could be found by either macroscopical or microscopical examination. Most of the glomeruli were in a state of arrested development. The connective tissue was most abundant near the hilum around the calices, which were partially obliterated. The mucous membrane of the calices and of the renal pelvis was atrophied. The ureters were contracted, but were not obliterated.—*Norsk Magazin for Lægevidenskaben*, April, 1900.

The Thyroid Gland in Infective Diseases.—Odoacre Torri, from the result of experimentation, concludes that there is hypersecretion of colloid substances in the gland, in acute or chronic infective diseases, as well as marked epithelial proliferation and an abundant neoformation of glandular tissue. Interstitial inflammatory processes, such as abscesses and tubercles, are rarely met with in the gland. The colloid substance has the property of destroying micro-organisms. The epithelial proliferation and the hypersecretion of colloid substances are due to a toxic product of the infective process, perhaps caused by destruction of the micro-organisms by colloid substance, or brought to the gland by the circulating blood.—*Il Policlinico*, May 15, 1900.

The Koplik Sign in Measles.—K. Manasse states that in three cases in which he could determine the presence of the peculiar eruption described by Koplik, measles followed in the course of twenty-four hours; in one case in which it was present, no exanthem followed, while two cases of undoubted measles did not present the sign at all. The sign in the latter cases was as typical in appearance as in the first group. Manasse is therefore of the opinion that, while the Koplik spots are frequently valuable as a forerunner of measles, they cannot always be depended upon nor are they pathognomonic.—*Münchener medicinische Wochenschrift*, June 5, 1900.

A Case of Cured Tuberculous Cerebro-Spinal Meningitis.—M. Henkel reports the case of a child aged ten years (male), who presented the symptoms of this affection. Some of the spinal fluid was withdrawn by puncture and gave positive evidence of the presence of tubercle bacilli. The case ran a long course, but finally recovery took place. The only remedy given internally was calomel. In addition, daily baths at 28° R. were given for ten minutes, the water cooling to 24° R.—*Münchener medicinische Wochenschrift*, June 5, 1900.

An Overlooked Cause of Pulmonary Lesion Suggesting at the Outset Tuberculosis.—P. de Champeaux records the case of man who came under observation with all the symptoms of initial pulmonary tuberculosis. After he had been watched for some time, the presence of a small laryngeal polyp was made out. Removal was somewhat difficult, but after the tumor was finally disposed of all the pulmonary symptoms abated and the patient made a good recovery.—*Revue Hebdomadaire de Laryngologie, etc.*, No. 14, 1900.

The Surgical Treatment of Primary Renal Tuberculosis, with a Consideration of the Results Obtained by Operation.—Otto G. Ramsay has collected the majority of the reported cases of operation and tabulated them. The following conclusions seem justified from the study, both of the individual cases and from the statistics which were gathered: (1) That in renal tuberculosis some form of surgical treatment is always indicated; (2) that this surgical treatment may have a palliative or curative effect in view, depending upon the condition of the patient and the extent of the disease; (3) that nephrotomy as a palliative operation for the immediate relief of dangerous symptoms is most valuable, and that it does not preclude a later nephrectomy; (4) that resection of the diseased part of the kidney is contraindicated in every case of renal tuberculosis; (5) that nephrectomy or nephroureterectomy is indicated in every case in which tuberculosis has not developed in other organs, or when there is no fatal disease of other organs; (6) that tuberculosis of the bladder or a small focus of tuberculosis in one lung are not considered contraindications to nephrectomy; (7) that primary nephrectomy or nephroureterectomy, when performed in suitable cases, has been followed by final cure in fifty-six per cent. of the cases operated on; (8) that with the present advances in the methods of examination and in the technique of operations, the percentage of final cures should be materially increased.—*Annals of Gynæcology and Pediatry*, June, 1900.

Pelvic Pain from Impacted Ureteral Calculi.—Septimus Sunderland believes that many cases of persistent pelvic pain are caused by a stone in one or the other ureter, although the pain is assigned to uterine or ovarian trouble or perhaps to some neurosis or hysteria. If the pain is on the right side, the appendix may be suspected. Diagnosis may be made by *x*-ray, palpation of abdominal parietes, palpation of the ureters, and the inspection of the orifices of the ureters through the cystoscope. Finally the ureters may be sounded through the bladder. The medical treatment is the same as for renal stone. As to surgical measures, if the stone projects into the bladder from the orifice of the ureter it must be removed through the bladder. Fenwick teaches that a stone lodged in the lower part of the ureter within the last two inches will sometimes set up symptoms precisely like those of stone in the bladder, that is to say, bladder irritation and spasm. If the stone can be detected by bimanual vaginal examination in the lower three inches of the ureter, but does not project into the bladder, it can be

safely extracted by incising the roof of the vagina in the female. If the stone is located at or about the pelvic brim, Fenwick recommends the abdominal incision used for ligature of the common iliac artery. The peritoneum having been raised, the lower end of the ureter is reached extra-peritoneally. For stone in the upper third of the ureter, the ordinary lumbar renal incision is indicated.—*Medical Press and Circular*, May 30, 1900.

Concealed Tuberculosis of the Tonsils.—F. Baup has repeated the experiments so frequently made by various observers during the last few years, finding tuberculosis present only once in forty-eight cases. He believes that we may distinguish three forms of this condition—a common form described by most authors, characterized in a general way by isolated or grouped tubercles more or less caseous and surrounded by a zone of lymphoid tissue which is but little changed; an indefinite infiltration but one showing without question the presence of the bacillus; and possibly a sclerotic form which represents a step toward repair. Baup discusses also the relation of this form of tuberculosis to adenopathy, to pulmonary tuberculosis, and to tuberculous meningitis.—*Annales des Maladies de l'Oreille, du Larynx, etc.*, May, 1900.

Splenic Hypermegaly with Hepatic Cirrhosis.—Professor Cardarelli reports the case of a man aged thirty-three years, suffering from anæmia and weakness. The abdomen was ascitic and tense, without œdema of the lower limbs. The spleen was notably enlarged, the liver markedly reduced. The urine was scanty, saffron colored, rich in uro-erythrin. The author holds that the affection should come under the head of hepatitis of splenic origin. He also believes that in cases of chronic and incurable splenic tumors, when the spleen not only does not perform its functions properly but threatens infection to other organs, we should not hesitate to perform splenectomy.—*Revista Critica di Clinica Medica*, May 5, 1900.

Hay Fever; its Preventive Treatment.—W. C. Hollopeter is a firm believer in the local origin of this disease. He removes polyps, hypertrophied turbinates, etc., straightens deviated septa, and thoroughly irrigates the nose and naso-pharynx with a warm Dobell solution. The whole mucosa is then brushed with cotton carrying a saturated solution of boric acid. Suprarenal extract may be added to a boric-acid solution and the whole used in spray. Immediately after the foregoing, an oily covering is applied. The one preferred by the author has for its base liquid petroleum, and contains in solution camphor, menthol, and palmetto oil. Finally, after the treatment is finished, the patient is made to wait quietly a few minutes before going out into the air.—*International Medical Magazine*, June, 1900.

Primary Epithelioma of the Tonsil.—The patient of J. M. Ingersoll was an Irishman aged forty-two years, whose right tonsil began to enlarge slowly without apparent cause. Twice the enlargement was amputated with a tonsillotome before Dr. Ingersoll saw the case, which was thirteen weeks after the swelling first became apparent. Pain had now become very severe. The tonsil was covered by a fairly firm, irregular, fungoid mass, projecting out about 2 cm. beyond the anterior pillar. The whole surface presented an uneven, cauliflower-like appearance and was covered by a muco-purulent secretion. The mass extended upward on to the soft palate, involving both the anterior and posterior pillars; it also followed the anterior pillar downward and extended on to the tongue; posteriorly the growth extended along the posterior pillar downward to its attachment to the pharyngeal wall, but the wall itself was not involved. The surrounding tissue was inflamed and infiltrated. The lymphatic glands at the angle of the jaw, on the right side, were involved. Operation was refused, and death followed in a short time.—*The Laryngoscope*, June, 1900.

When to Operate in Appendicitis, and Why.—John B. Murphy believes with most surgeons that we are unable to state in the first twenty-four hours what the course of a case is going to be. He believes that every honest man admits that the mortality of appendicitis is greater than ten per cent. He believes that every competent surgeon thinks that he can operate on a case of appendicitis, when the disease is still confined to the wall of the appendix, with a mortality of two per cent. or less. Therefore he concludes that we are not justified in holding a single case of appendicitis beyond the first twenty-four hours after the diagnosis is made, and that in an enormous percentage of cases the diagnosis can be made as absolutely in the first twenty-four hours as it can at any other time.—*International Journal of Surgery*, June, 1900.

Surgical Treatment of Chronic Empyema.—Francis Reder says that an empyema should never be allowed to become old if it can be avoided; after an expiration of six weeks an accumulation of pus in the pleural cavity may be looked upon as chronic. The pathological conditions of chronic empyemata require heroic measures on the part of the surgeon to stay their progress. Even weak patients bear well an extensive resection of the ribs when skilfully and dexterously performed. The author describes in detail the operation for a total empyema. The convalescence is slow and protracted. It is during this period that great good can be accomplished by the various forms of graduated exercise and respiratory gymnastics intelligently practised.—*International Journal of Surgery*, June, 1900.

Enteroptosis with Factitious Urticaria.—G. Gordon Campbell relates a case in which, though there was marked enteroptosis, the patient sought relief only for red blotches which followed any slight stimulation of the skin. Itching had begun three years before, after childbirth. It is relieved by the warmth of the bed. Stinging and burning accompany the outbreak of red blotches upon washing the face, etc. Emotional blushing comes out in similar scattered patches. Factitious urticaria is brought out by drawing a blunt pointed instrument over the back. This is shown in a photograph. In a second picture is illustrated the enteroptosis. There is deformity at the waist from tight lacing. A rounded prominence is seen in the lower abdomen resembling pregnancy in the fourth or fifth month. The right kidney can be felt an inch below the level of the umbilicus and midway between it and the crest of the ilium, while what is presumably the left kidney can be felt at about the level of the umbilicus. An abdominal supporter gives a feeling of strength and relief. It is believed that the enteroptosis bears a causal relation to the erythema and factitious urticaria.—*Montreal Medical Journal*, June, 1900.

Some Cases of Relapse in Diphtheria.—Carlo Comba considers that the causes of relapses are twofold. In the first place there may be a loss of the immunity acquired in the first attack. The exact nature of the immunity is not yet known, but Escherich and Klemensiewicz have shown that the blood serum of persons who had just had a diphtheritic attack has the power of attenuating and even of neutralizing the diphtheritic toxin. How this natural or acquired immunity is lost is not yet understood; probably, however, by the intervention of other infective diseases. In the second place, certain local conditions are favor-

able to the occurrence of diphtheria and its relapses—such, for instance, as repeated inflammations of the pharyngeal mucosa, hypertrophy of the tonsil, etc., which would tend to reduce the power of resistance against infective germs.—*Rivista Critica di Clinica Medica*, June 2, 1900.

A Case of Acquired Stenosis of the Pulmonary Artery.—A. Kasem-Beck is led by the great rarity of a stenosis of the pulmonary artery coming on in the later years of life, and the marked difficulties of an exact diagnosis, to publish a case. The patient was a laborer fifty years old, who showed compensatory disturbances of the heart, œdema, ascites, cyanosis, and expiratory dyspnœa. There were bilateral hydrothorax, hydropericardium, and dilatation of the right ventricle. The physical signs are given and the few undoubted cases in literature are referred to. The result of the autopsy is appended.—*Centralblatt für innere Medicin*, June 9, 1900.

Mucous Disease.—Philip F. Farbour defines this disease as being characterized by an irregularly occurring profuse discharge of mucus from the intestinal tract, accompanied by more or less marked nutritional disorder. In its treatment the inherited gouty or uric-acid tendencies must be counteracted. Food should be simple and easily digested; fats and carbohydrates should not be taken. Hygienic surroundings should be of the best. Cold sponging with brisk rubbing is of value. Bitter tonics are used to relieve the patient of the accumulations of mucus. Bismuth has a sedative and mildly astringent action. A combination of hydrastis and sanguinaria will be found to have a decidedly curative influence. Copper arsenite has a decidedly antiseptic action.—*Virginia Medical Semi-Monthly*, June 8, 1900.

Hysteria in the Child.—Ruggiero Lambranzi reports two cases. The first was that of a boy aged nine years, who at times had a spasm of the hand which would close the fingers so tightly that they could be opened only by force. The symptoms did not point to organic lesion. The author placed a bit of money in the child's hand, and told him that if he succeeded in extending his fingers without the aid of his other hand, he might keep the pennies. The treatment, which the author calls a new kind of metallotherapy, was successful. The second case was one of blepharospasm in a little girl aged eleven years, the attacks lasting about three days, and being accompanied by amblyopia and headache. A visit to the clinic and the manœuvres of the objective examination caused a cessation of the trouble.—*La Riforma Medica*, May 30 and 31, 1900.

The Medical Treatment of Gall Stones.—Edward S. Stevens believes that it is frequently difficult and often impossible to make a positive diagnosis of gall stones. He says that there is no known medicine by means of which a solution of gall stones can be effected by any of the ordinary means of administration. The introduction of a cannula into the gall bladder for the purpose of sounding for stones, introducing solvent remedies, or withdrawing fluids, is dangerous when compared with the amount of good likely to be accomplished, and should not be practised. The practice of attempting to empty the gall bladder by massage is dangerous. There is but one safe and radical cure for gall stones, and that is by cholecystotomy or some similar surgical operation.—*Virginia Medical Semi-Monthly*, June 8, 1900.

Symptomatic Diagnosis of Valvular Obstipation.—Thomas C. Martin says that valvular obstruction below the recto-sigmoidal juncture is characterized by straining at stool for the passage of solid fæces. Obstruction at the recto-sigmoidal juncture is characterized by long intervals between the acts of defecation, by an occasional passage of a quantity of fæces without much straining, and by tenderness and a sense of fulness in the left iliac fossa and lower abdominal regions. Valves sometimes interlock and form an almost impassable barrier to the descent of the fæces. Hypertrophy of the rectal valve is characterized by the almost sudden establishment of obstipation. The condition is initiated by a sense of gentle aching and moderate heat in the sacral region, by aching down the thighs, and by discharges of a small amount of viscid mucus. Fibrosis of the rectal valve is characterized by a very gradual development of the obstipation. Valvotomy cures.—*Virginia Medical Semi-Monthly*, June 8, 1900.

Acute Osteomyelitis.—E. Koch says that within the past ten years we have come to look upon the etiology, frequency, etc., of acute osteomyelitis in a new light. Many former confusing instances of joint affection would now be referred to this condition. Small nodes on the ribs can cause severe empyema of the pleural cavity, and acuted intracranial abscesses by the severity of their symptoms mask a primary osteomyelitis of the skull. An instance of osteomyelitis of the sternum in a man thirty years old is recorded, in which the symptoms suggested actinomycosis of the lungs or tuberculous bone disease. There was here present, as in the five recorded instances in literature, a pure primary osteomyelitis of the sternum, but the other patients were nearer the typical age. The patient was successfully operated upon. In view of the possibility of mediastinitis a primary free trepanning of the sternum and early removal of the entire diseased bone would be the most rational form of treatment.—*Münchener medicinische Wochenschrift*, June 19, 1900.

Infantile Amaurotic Family Idiocy.—J. H. Claiborne, Jr., gives the report of a case and its autopsy, reviewing the original observations of Waren Tay upon changes at the macula lutea, and subsequent descriptions of the same ophthalmoscopic picture by other observers. The writer has had five cases under his notice. His observations agree with those of Sachs, who in 1898 reviewed the subject and tabulated twenty-nine instances. The case in question was that of a female infant of eleven months. There was double ophthalmoplegia; the left eye was farther out and the left lid lower than the right. The father had phthisis. Great somnolence developed, and the child could not hold up its head or sit up straight. At the macular region in each eye there was a marked white area with the macula lutea in the centre like a cherry-red point. At the autopsy there was found a tuberculous tumor of the corpora quadrigemina the size of a hickory nut, with tuberculous deposits in the lungs, bronchial and mesenteric glands, liver, spleen, and kidneys. These children are born apparently healthy and remain so for several months; there are then sluggishness and somnolence, with irregular movements. The eye picture resembles that seen in embolism of the central retinal artery. The optic disc is at first normal and later shows complete atrophy. Death is invariable, usually before the end of the second year. The majority of the parents have Hebraic blood, a large number being of Polish-Hebraic origin. It seems reasonable to regard the changes in the nervous system as due to arrest of development. Tuberculosis may be a probable general cause. The question is raised whether the symptoms are not those of a disease not yet recognized, rather than constituting a definite entity.—*Pediatrics*, July 1, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 14, 1900.

YELLOW FEVER IN MEXICO AND IN CENTRAL AND SOUTH AMERICA.

AN exhaustive account was published in "Public Health Reports," June 15th, of the sanitary condition of Central American and Colombian towns with special reference to their geographical position and the possible routes by which yellow fever is conveyed from one to another, and the dangerous lines of communication with the United States. The fact is pointed out that the history of yellow fever can be traced back to many years before the invasion by Cortez, and that since the first settlement by the Spanish the fever situation has apparently undergone no improvement. Vera Cruz—which has been since its foundation a hot-bed of the disease, and which last year had a mortality rate of six hundred and seventy out of a population of thirty thousand—is undoubtedly the Mexican port most to be dreaded by the United States as a source of infection. Fortunately the quarantine regulations are strict, and all freight and passenger traffic, with the exception of a few steamers which trade between Vera Cruz and Pascagoula, Miss., and New Orleans, has been deflected to the northern ports. The bulk of the passenger traffic goes to or through Havana, and, as the writer of the report remarks, the danger of infection of Havana from this source is a problem that can be solved only by an absolute quarantine or the hearty co-operation of the Mexican health authorities. The railroads are a source of dangerous communication, and it is only by constant vigilance on the part of the Marine-Hospital service inspectors on the border that yellow fever is kept out of the United States so successfully as is at present the case.

"Public Health Reports" reviews at length the situation in the Central and South American towns, which by reason of their location and on account of the intercourse between them and this country are ever a probable means of disseminating yellow fever through parts of the North American continent. The author of the report says that the prevalence of Chagres and yellow fever on the isthmus of Panama during the construction of the canal by the French should be borne in mind, should the United States Government undertake to build this canal. There is an infected territory from ocean to ocean, and the importation of a number of non-immune workmen would be the signal for an outbreak of an epidemic of yellow fever. The yellow-fever infection is there, and the Chagres will come when the excavations commence. The whole isthmus should be disinfected before any workmen are imported, and a thoroughly equipped, strictly enforced maritime quarantine maintained at Panama and Colon. This should be done not only for the protection of the army of workmen that will be necessary for such an undertaking, but for the protection of the infectable States that will be in direct communication with the isthmus just as soon as timber and supplies are needed for the construction of the canal. The route of the Nicaraguan Canal is not infected with yellow fever, and there is no history of any infection having been in the country for many years. There should be suitable quarantine stations maintained at each end of the canal, and they should be the first things constructed. It matters not which route is selected, there will be a rush of people from all over Central and South America coming from infected localities and bringing the infection with them.

Yellow fever is now extremely prevalent in Vera Cruz and along the southern coast line of Mexico and the Central American States. It is therefore fitting that attention should be called to the unsanitary conditions of these towns, and to the importance to the people of this country that measures should be taken to render them healthy, especially with a canal at Panama or Nicaragua in view. No serious attempt has ever been made to extirpate or check yellow fever in any of the South American republics. The towns along the coast and the ports are, as a rule, the most unhealthy localities, and the physicians furnished by the government are, owing to these insalubrious conditions and to poor pay, by no means of a high class. Taking then into consideration the constant menace the existing state of affairs in the South American republics is to the health of the inhabitants of the United States, it is somewhat a matter for wonder that the government does not exert its persuasive powers or even exert some pressure to induce the republican governments to initiate a policy of sanitary reform.

THE SIGNIFICANCE OF TUBERCLE BACILLI AND OTHER BACTERIA IN THE SPUTUM.

IN the presence of symptoms and signs of disease of the lungs the discovery of tubercle bacilli in the sputum may be regarded as indicative of the existence of pulmonary tuberculosis. Failure to find the bacilli, even on repeated examination, cannot, however, be accepted as evidence against pulmonary tuberculosis. The bacilli can appear in the sputum only if breaking down of tubercles has taken place and communication exists between the ulcerated tissues and the air passages. They are thus absent, as a rule, in cases of miliary tuberculosis; and, sometimes, in cases of early or even advanced tuberculosis careful and oft-repeated examination may fail to disclose their presence. On the other hand, the persistent expectoration of large numbers of bacteria is indicative of the presence of a cavity, although sometimes the number varies widely

accordingly as the cavity communicates with the air-passages or not. In an address on the diagnostic and therapeutic significance of tubercle bacilli and other bacteria in the sputum, Brieger (*Berliner klinische Wochenschrift*, No. 13, 1900) points out that a factor of great importance in cases of pulmonary tuberculosis is the matter of mixed infection. There is reason to believe that to this is due principally the violent febrile movement so often observed in cases of advanced tuberculosis. Pure, uncomplicated local tuberculosis of the lungs is, it is thought, almost wholly unattended with fever, and the sputum is, besides, rather scanty.

The micro-organisms principally responsible for secondary infection are streptococci, staphylococci, and pneumococci, singly or in association. The hectic fever, with chills and night sweats, is believed to be due principally to streptococci, while to the staphylococci are attributed the suppurating and softening processes in tuberculous lungs. Influenza bacilli also are not rarely found in the sputum from tuberculous patients, and they are highly capable of aggravating the tuberculous process. The bacillus pyocyaneus and the micrococcus tetragenus are occasionally found in sputum from tuberculous patients. From the evidence the rôle of mixed infection would seem to be the conversion of pulmonary tuberculosis into pulmonary consumption.

In the prophylaxis of mixed infection in cases of pulmonary tuberculosis especial attention should be given to the care of the mouth. Inhalations of aromatic oils, especially peppermint oil, probably exert a useful therapeutic influence in this direction. Fresh air rich in ozone and hydrotherapeutic measures may also be productive of good by neutralizing the evil effects of mixed infection.

INSANITY IN VIRGINIA.

Virginia can lay claim to the proud distinction of having founded the first institution exclusively for the insane upon this continent. According to Dr. Drewry, superintendent of the Central State Hospital, Petersburg, Va., who writes interestingly on the matter, in 1769 the House of Burgesses provided for a building for the insane at Williamsburg, then the capital of the colony. This event preceded by thirty years the revolution in the treatment of the insane introduced by Pinel of France and Tuke of England. In 1802 Virginia provided a second public institution for her insane at Staunton, and in 1870 she organized the first asylum exclusively for the colored insane in the world. Dr. Drewry states that at the present time the population of Virginia is about 1,700,000, two-thirds being white and one-third colored. Of these 3,100 have been adjudged insane, a ratio of one in nearly every 600 of the population. The ratio in the whites is slightly larger than that in the negroes, though in recent years insanity has increased more rapidly among the latter than the former. The following statistics are significant: On October 1, 1887, there were in the State hospitals 1,171 white and 434 colored insane; total 1,605. There are now 1,950 white and 870 negro insane at these institutions, a total of 2,820, showing an increase of 1,215, or an annual net gain of 92 in the hospital population. From the above figures it will be gathered that as in all parts of the world insanity in Virginia seems to show an increase, and in consequence accommodation in the State hospitals for the unfortunates suffering from that disease is altogether inadequate. It is stated that during the past two years 182 colored and many white insane have died in jail or at their homes while waiting for vacancies to occur in the hospitals.

Attention has been drawn in the Medical Record on several occasions to this condition of affairs, which prevails to a greater or less extent throughout the United States. The fact has been demonstrated that, in addition to being an expensive manner of treating lunatics, it is also inhuman to a degree. In the earlier stages of insanity, if the malady is treated intelligently the chances of recovery are favorable, while if an opposite course is pursued the majority of cases will become incurable and chronic. The practice of condemning an insane person to jail like a common criminal is unworthy of a rich, civilized, and Christian land.

THE MIDWIVES BILL IN ENGLAND.

The midwives bill introduced into the English House of Commons early in the session has passed the second reading and been amended by the standard committee on law. It, therefore, seems certain that it is within measurable distance of being put into force. The bill would appear to have divided the medical profession of England into two camps, the larger of which is altogether opposed to the projected licensing of midwives, while the lesser division, appreciating the fact that some such legislation is needed and must come, and recognizing the futiliity of kicking against the pricks, have concluded that the wisest course is to bow to the inevitable and to concentrate their energies on obtaining as perfect a bill as is possible.

Dr. Glover, a prominent member of the British General Medical Council, and who is with Professor Horsley the most conspicuous advocate of the latter mode of dealing with the question, read a paper at the conference on medical organization recently held at Manchester, in which the situation viewed from this standpoint is clearly indicated. He states the facts to be as follows: First, that midwives exist, and that they attend on a low estimate two hundred thousand cases. Secondly, that the title "midwife" exists and is recognized by law, and can be taken by any woman and used for making a living. Thirdly, that any woman, however drunken, or ignorant, or dirty, may without hindrance use this title and under its name may do an incalculable amount of harm. Dr. Glover is of the opinion that either very cheap midwifery must be done by physicians, or midwives must do it; that opposition to all legislation on midwives means the continuance of the old midwife, and finally that public and parliamentary opinion is too decided in favor of legislation for things to remain as they are.

The supporters of the bill further hold that the General Medical Council may be relied upon to do its best in the interests of the medical profession.

The opposition to the bill as it stands is undoubtedly strong among medical men throughout England. This was plainly shown by the fact that out of sixty thousand and three hundred practitioners who responded to a request from *The Lancet* for an expression of their views, four thousand were against the measure, and only thirteen hundred and eleven declared in its favor. The contention is made that a training of but three months is insufficient time to fit a person to undertake the seriously responsible duty of attending upon a parturient woman, even though the midwife be authorized to call in a qualified practitioner in cases of abnormal labor. There are also many other features of the bill to which grave exception is made. There is no doubt, however, that legislation on midwives will in the near future be enacted in England, whether for good or evil time alone can prove. Our opinion on the subject as concerns this State, which we have as yet seen no cause to withdraw, has been already expressed in these pages.

News of the Week.

Enraged Anti-Vaccinationists. — Half a dozen or more members of the American Anti-Vaccination Society met recently in New York, and decided that McKinley and Roosevelt must be defeated at the polls in November unless before that time Governor Roosevelt has exculpated himself of complicity in the recent compulsory vaccination by the public health authorities of one hundred negro laborers in the smallpox-infested brickyards at Stockport, near Hudson, N. Y. This formidable society, which now threatens to enter into politics, is composed largely of what doctors in their case reports are wont to call females.

The Dangerous Fourth.—The Chicago *Tribune* of July 5th contained a partial list of the casualties resulting from the insane method which Americans have of demonstrating their patriotism on the national fête day. According to reports received from one hundred and twenty-five cities, thirty persons were killed and thirteen hundred and twenty-five injured. The toy pistol and the toy cannon are shown to have done as deadly execution as sometimes has been done in war by those loaded with bullets and canister and aimed to kill. Skyrockets, powder explosions, and the premature discharges of cannon help to complete the list of mishaps. Out of this total of thirteen hundred and twenty-five persons hurt in an attempt to be patriotic, four hundred and forty-two can attribute their injuries to firecrackers and dynamite torpedoes. The deadly cannon firecracker did most of this execution. Out of one hundred and fifty-two injured by firearms in sixty-seven cities, the toy pistol caused one hundred and five. Gunpowder explosions caused the injury of one hundred and eighty-seven. Many of the injuries included in the lists were reported as prospectively fatal. In several instances persons were killed through runaway accidents, due directly to fireworks. A fire loss of $123,327 was caused by fireworks, in addition to the injury to human life. To the number of deaths caused directly by these explosive accidents must be added those yet to occur from tetanus due to infected wounds.

Dr. Charles F. Chandler, professor of chemistry at Columbia University, has received the degree of D.Sc. from Oxford.

The Hospital Ship "Maine," equipped by the Anglo-American committee for service in the South African war, has returned a second time with wounded and invalided soldiers to Southampton. The committee has now offered the British government the use of the ship for service in China, and this offer has been accepted. The vessel will sail soon with the same staff she had in South Africa. She will be used as a base hospital ship, but it has not yet been decided at what port she will be located.

The Osteopaths held their third annual meeting in Chattanooga, Tenn., during the first week in July, and devoted much of the time to rejoicing over the fact that the legislatures in several of the States have passed bills legalizing their dealings with the sick. The curious title of one paper was "The Fake Osteopathist and How to Deal with Him." A fake osteopathist must be about on the level of an anti-Eddy Christian Scientist.

A Curious Acquittal.—In the court of assizes in Brussels, a few days ago, Sipido, the youth who attempted to assassinate the Prince of Wales while the latter was passing through the city en route to Copenhagen, and his three accomplices were acquitted on the ground that they were too young to understand the gravity of their acts. The four lads were all between sixteen and seventeen years old. The public prosecutor asked the court to commit Sipido to a reformatory, but the application was refused. It would be interesting to know when, in the opinion of a Belgian judge, the age of reason or of responsibility for criminal acts is reached.

The Health of Manila.—A report of the health conditions in Manila, which has recently been issued by Major G. L. Edie of the army medical department, shows that American sanitary methods are as happy in their results in the Philippines as they are in the West Indies. According to this report, the death rate in Manila from October, 1899, to June, 1900, was 28 per 1,000. The total number of deaths was 8,535, of which 180 were caused by the plague and 1,073 by intestinal disease. The sanitary conditions have been greatly improved in the city since the end of the organized rebellion has permitted the health authorities to give more attention to such matters.

Medical Missionaries in China.—The following are among the American medical missionaries in the disturbed districts of China concerning whose safety grave fears are entertained: Dr. John M. Inglis, of Peking. Dr. Cortlandt Van Rensselaer Hodge, of Pao-Ting-

Fu, a native of Philadelphia and a graduate of the medical department of the University of Pennsylvania in 1897. Dr. Maud A. Mackey, of Pao-Ting-Fu, a native of Evanston, Ill. Dr. G. Yardley Taylor, of Pao-Ting-Fu, a native of Taylorsville, Pa. Dr. Virginia Murdock, of Peking, a native of Zanesville, Ohio, and a graduate of the medical department of the University of Michigan in 1887. She was formerly in practice in Chicago. Dr. James H. Ingram, of Tung-Chow, a native of Mansfield, Ohio, and a graduate of the medical department of the University of Pennsylvania in 1883. He formerly lived in Vineland, N. J. Dr. George D. N. Lowry, of Peking. Dr. Rachel R. Benn, of Tien-Tsin. Dr. Anna D. Gloss, of Peking. Dr. M. S. Barrow, of Tai-Nan. Among those believed to be safe are Drs. Charles Lewis and Edna B. Parks, of Se-Nan-Fu; Dr. W. R. Faries, of Wei-Hien; and Drs. C. F. Johnson and E. E. Fleming, of I-Chow-Fu. Dr. Sylvester G. Hill, United States vice-consul at Tien-Tsin, is a dentist, a graduate of the Philadelphia Dental College. He was born in Muscatine, Ia., in 1856.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending July 7, 1900. June 30th.—Surgeon O. D. Norton detached from the *Monadnock* and ordered to duty with marines at Taku, China. July 2d.—Medical Director G. W. Woods will be detached from naval hospital, New York, and placed on retired list, August 24, 1900, having reached the age of sixty-two years. July 5th.—Passed Assistant Surgeon F. C. Cook detached from the naval hospital, Norfolk, Va., and ordered to the naval hospital, Washington, D. C. Passed Assistant Surgeon J. F. Leys detached from the *Franklin* and ordered home and to wait orders.

Summer Mortality.—The influence of the intense heat of the past week upon the death rate is shown by the fact that for the week ended July 7th there were reported to the Philadelphia bureau of health 544 deaths—47 more than for the preceding week and 109 more than for the corresponding week of the previous year. Of the whole number nearly one-third occurred in children under the age of five years—73 from cholera infantum, 30 from marasmus, 23 from convulsions, 24 from inanition, and 7 from teething. Besides 5 deaths are attributed to sunstroke, 4 to dysentery, 3 to diarrhœa, 9 to old age, and 6 to debility. In New York during the first week in July the daily average of deaths of children of five years of age or under was 52 in the boroughs of Manhattan and the Bronx, and 45 in Brooklyn. This is a high infant death rate for New York.

The Nathan Straus Milk Charity.—This charity, which was organized in 1893, in a little shed on a dock at the foot of East Third Street, now occupies a large two-story building and dispenses during the year from various branches some five hundred and fifty thousand bottles of pasteurized milk. In order to furnish a food better adapted to very young or sick infants, two new modifications have recently been prepared, one intended for sick infants and the other for healthy infants; the former is a dilution of milk with three times its bulk of water and lime-water with sugar added so as to provide a food containing one per cent. fat, five per cent. sugar, and one per cent. proteids; this is dispensed in three-ounce bottles. The second new modification, intended for healthy infants of early age, represents two per cent. fat, five per cent. sugar, and one per cent. proteids, also dispensed in three-ounce bottles. Another modification containing about four per cent. fat, seven per cent. sugar, and two per cent. proteids is dispensed in six-ounce bottles. Whole milk is also dispensed in pint bottles. All this milk is accurately pasteurized in hygienic nursing-bottles at 75° C. (167° F.), is rapidly cooled, and is delivered to the branch depots in refrigerator wagons. With each bottle a sterile nipple is supplied. The milk will be supplied free to any applicant who presents a statement from a physician that she is unable to pay for it. Such applicant must, however, leave a deposit to insure the return of the bottles.

Dr. Karl Lange, of Copenhagen, died recently at the age of sixty-six years. He was professor of pathological anatomy at the University of Copenhagen, and editor of the *Hospitals Tidende*, a weekly medical journal.

The British Army Medical Scandal.—The government has appointed on the committee to investigate the South African hospital charges Dr. Daniel J. Cunningham, of Trinity College, Dublin, Dr. Henry M. Church, of Edinburgh, and Lord Justice Romer.

Compulsory Vaccination Legal in Pennsylvania.—By a decision of court in favor of the defendant in a suit instituted by a citizen of Philadelphia against the principal of a school to compel the admission of a pupil without vaccination, the legality of compulsory vaccination in the schools of Pennsylvania is sustained.

Thermometry in Germany.—An order has been promulgated that after January 1, 1901, the use of the Centigrade thermometer shall displace that of the Réaumur in Germany. In medicine the Centigrade scale has been almost universally used for a long time. The freezing-point on both scales is 0, but the boiling-point is 100 on the Centigrade, while it is 80 on the Réaumur.

The Vienna Society of Obstetrics and Gynæcology is a society of about fifty members. It meets at the call of the president, Dr. Libotzky, in the amphitheatre of the No. 2 (Chrobak) clinic in the General Hospital. This seems a peculiarly fitting place, for not only are there hundreds of cases of obstetrics and gynæcology above, below, and on either side, but frequently during the evening the speaker's voice is drowned by the cries of women in labor.

Infanticide Not a Capital Offence in France.—The law regarding infanticide in France has been amended by the senate, the punishment for the crime being made imprisonment for a term of years instead of death. The reason urged for the change was that

juries would not convict in trials for infanticide, even when guilt was established, so long as the penalty was death.

Obituary Notes.—Dr. Charles P. Judkins, of Cincinnati, died on July 1st, at the age of fifty-seven years. He was a graduate of the Miami Medical College in 1867, and had practised continuously in Cincinnati since that time. He belonged to a family of physicians, his father, two uncles, two brothers, and a cousin all being members of the medical profession.

Dr. Thomas P. Edwards died at his home in Newark, N. J., on July 4th, of heart disease, at the age of thirty-nine years. He was born in Marcy, N. Y., and was graduated from the medical department of the University of New York in 1885.

Dr. Gerald Freeman, surgeon of the Allan Line steamer *Carthagenian*, was lost overboard from the steamer in Halifax harbor on July 6th. The steamer was entering the harbor on her return voyage from Liverpool. Dr. Freeman studied medicine in Dublin.

Dr. J. L. M. Cardeza died at Claymont, Del., on June 28th, in an apoplectic attack, at the age of seventy-nine years. He was a graduate of the medical department of the University of Pennsylvania.

Dr. Franklin Gauntt died at Burlington, N. J., on July 7th, in the seventy-seventh year of his age. He was graduated from the medical department of the University of Pennsylvania in 1847. He was a surgeon in the war of the Rebellion and at the time of his death one of the surgeons to the Pennsylvania Railroad.

Obituary.

ALEXANDER J. C. SKENE, M.D., LL.D.,

BROOKLYN, N. Y.

Dr. Alexander J. C. Skene, of Brooklyn, died on the night of July 4th, at his summer home at Highmount, in the Catskill Mountains. His death was unexpected, for although he had been suffering for some time from an ailment of the heart, nothing was suggested by his condition to cause his family or his friends concern. Dr. Skene was born in 1838 in the Parish of Fyvie, Aberdeenshire, Scotland. He came of a noted Scotch family, many of the members of which had been closely identified with much of the history of Scotland. He came to this country when nineteen years old, and soon after his arrival he entered the University of Michigan. From there he went to the Long Island College Hospital in Brooklyn, from which institution he was graduated in 1863. He offered his services to the government in the Civil War, and went to the front as a surgeon. While with the army he evolved a plan for a hospital corps which is to-day in use in the army and the National Guard.

After the war Dr. Skene returned to Brooklyn and was appointed adjunct professor of medicine at the Long Island College Hospital Medical College. For many years he was professor of gynæcology and dean of the college, but resigned from the faculty about a year ago in order to devote his energies to the establishment of the Skene Hospital for Self-Supporting Women. It was intended to open this hospital in the autumn of the present year.

Dr. Skene was a gynæcologist of great skill and was widely known through his writings on the diseases of women. He was formerly professor of gynæcology in the New York Post-Graduate Medical School, and had been president at different times of the American Gynæcological Society, the New York Obstetrical Society, and the Kings County Medical Society. He was a member of several other medical societies and was also a corresponding member of the Boston, Detroit, British, and Belgian gynæcological societies.

Dr. Skene was a lover of art and was himself a sculptor of fair abilities. He also had literary tastes and had published one novel.

JOHN ASHHURST, JR., M.D., LL.D.,

PHILADELPHIA.

Dr. John Ashhurst, Jr., died at Philadelphia on June 7th, at the age of sixty-one years. He was graduated from the department in art of the University of Pennsylvania in 1853, received the degree of A.B. in 1857, and that of A.M. in 1860, when also he was graduated from the medical department. In 1895 he received the honorary degree of doctor of laws from Lafayette College. Soon after the outbreak of the Civil War, and while still a resident physician in the Pennsylvania Hospital, Dr. Ashhurst was commissioned acting assistant surgeon and placed in charge of Cuyler General Hospital, Germantown, serving here and at the Chester United States Army General Hospital from 1862 to 1865.

Dr. Ashhurst was from 1863 to 1880 surgeon to the Episcopal Hospital. In 1870 he was appointed surgeon to the Children's Hospital, in 1874 consulting surgeon to the Hospital of the Good Shepherd, in 1875 consulting surgeon to St. Christopher's Hospital and to the Pennsylvania Institute for the Blind. In 1877 he was elected clinical professor of surgery in the medical department of the University of Pennsylvania and surgeon to the University Hospital. In 1887 he became surgeon to the Pennsylvania Hospital and in 1888 was appointed John Rhea Barton professor of surgery in the university.

Dr. Ashhurst was an able and voluminous writer, and he was a member and an officer in many medical societies.

Progress of Medical Science.

New York Medical Journal, July 7, 1900.

The Identification of the Blood of Individuals.—W. H. Birchmore has made a series of studies, the general results of which may be summarized as follows: The measurements of the blood of children show variations large in amount and not easily explained; there is no order in the changes, but in practice the result is as follows: Beginning in a child two years old, the variations became distinctly less during the time he was under observation. About twenty satisfactory counts were made, covering about one thousand corpuscles each, and each corpuscle was measured. In a boy of twelve years the variations were very small; as between two boys of this age, there was no question of the identity of any specimen examined. As to the degree of certainty obtainable, it seemed quite certain that a blood stain can be positively identified as belonging to the same blood as another given stain, or as not so belonging. In practice the question will usually take the form of a strictly limited inquiry: "Is the blood of this stain the same as the blood of that one?" or, "To which of these various blood stains does the blood of this stain correspond?" To both of these inquiries positive answers can be given. Within limits, the expert can say positively, "The blood stain A is not the same as that of stain B"; or he can say, "It is my opinion that the blood of stain A is the same as the blood of stain B."

Acute Traumatic Prostatitis of External Origin Involving the Bladder and Seminal Vesicles.—J. M. Thomson reports the case of a man, aged fifty-one years, who, as the result

of a bicycle accident, struck his perineum on the pommel of the saddle. Pain in the perineum and rectum became intense, while he experienced a sense of heat, fulness, and weight in the region of the bladder and along the floor of the urethra. Micturition soon became urgent, frequent, and painful; and defecation also, but to a milder degree. Bodily movement caused an exacerbation of pain, and even the sitting posture proved uncomfortable.

A Case of Typhoid Presenting Some Unusual Features.—The noteworthy points in this case, under care of C. E. Skinner, were: (1) A sudden rise of temperature; (2) persistent and obstinate constipation; (3) absence during the entire illness of bronchial symptoms and headache; (4) atypical color of stools; (5) acute pain in the left iliac fossa; (6) nausea and vomiting; (7) a severely painful myositis; (8) absence of eruption; (9) an excessively high temperature extending over ten weeks; (10) the gratifying effect upon the myositis of heat at a high degree.

Acute Gonorrhœal Arthritis, etc., of the Left Shoulder, which Necessitated Operation and was Followed by Rapid Recovery.—By J. C. Stinson.

Secondary Cataract: A Experimental Study.—By W. H. Bates.

The Unrequited Service of a Physician.—By A. N. Smith.

A Case of Hairpin in the Urethra.—By W. L. Brown.

The Boston Medical and Surgical Journal, July 5, 1900.

The Use of the Angiotribe.—J. H. Davenport describes the clamp first advocated by Doyen for controlling hemorrhage and subsequently modified. The instrument seems especially indicated in vaginal hysterectomy. His mode of employing it is described. There is almost no pain, practically no bleeding, and convalescence is easy and rapid, making the technique an advance in securing complete compression of the interstitial connective tissue with all its lymph spaces. The danger from secondary hemorrhage is slight, as indicated by many cases reported. The author's own experience relates to five operations in which it was employed with great satisfaction.

A Case of Morbid Fear.—J. W. Courtney speaks of the widely varying forms of fear encountered in neurasthenic subjects, and relates an instance in a young woman stenographer of neurotic ancestry who acquired such a pronounced fear of death as to have it dominate her entire existence. She was finally cured by tonic treatment (iron), hypnotic suggestion, tasks of memorizing, etc.

Remarks on the Surgery of Uterine Fibroids, with Special Reference to the Importance of Early Removal in the Young.—By M. H. Richardson.

Colostomy for Obstruction due to Malignant Disease.—By J. B. Blake.

Philadelphia Medical Journal, July 7, 1900.

Total Excision of the Scapula alone, and with the Arm (Interscapulo-thoracic Amputation): Partial Excision of the Scapula for Tumor.—J. J. Buchanan reviews the literature, classifies the cases, gives histories of his own cases, and describes Berger's method, which was followed with slight modification. The essential elements of this method are preliminary ligation of the great vessels and the formation of anterior and posterior flaps.

Medical News, July 7, 1900.

The Treatment of Tetanus.—Alexander Lambert reviews Thallmann's recent article and reports various experiments and observations. Tetanus wounds should be thoroughly cleansed with iodine trichloride, one per cent., or Gram's or Lugol's solutions, carbolic solutions (one and a half per cent.), cresol (one per cent.), formalin (one to two per cent.). Deep incisions should be made to make sure that no dirt or wads of cartridge are retained, as has been too often the case. We should aim at (1) speedy elimination of the poison; (2) the administration of physiological antidotes; (3) chemical antidotes to render the poison inert. The kidney action must be increased by free use of water. The best physiological antidote is chloral. Bromides, physostigmine, and antimony act in the same way by diminishing the intense reflex excitability of the central nervous system. The prognosis is in direct ratio to the shortness of the incubation period and to the rapidity and intensity of the development of the symptoms. There is no doubt that many cases of human tetanus could be avoided by preventive doses of antitoxic serum (10 c.c.) in cases of wounded persons in localities where tetanus prevails. In the records of fifty-two cases treated by intracerebral injections there was a mortality of over sixty-three per cent.

The Immunizing Cure of Hay Fever.—H. H. Curtis first tried to immunize a hay-fever subject by giving internally the watery extracts of certain flowers and their pollen. He has recently taken up the question anew, and reports some successful trials in this direction by administering solidago odorata and convallaria majalis.

The Hospital Governor and his Staff: Being a Glance at the Personnel of a Modern Hospital and a Plea for a Permanent Resident Staff.—By Thomas J. Hillis.

Significance of the Stool in Infantile Diarrhœas.—By William Edgar Darnall.

Journal of the American Medical Ass'n, July 7, 1900.

The Surgery of Biliary Calculi.—W. D. Haggard, Jr., discusses the surgical aspects of biliary calculi and gives the various operations which have of recent years been devised for their relief, and the bibliography of the subject. He gives a report of a case of colo-cholecystostomy for chronic catarrhal cholangitis with gall stones. He gives Robson's conclusions from experiments on a case of biliary fistula: (1) The bile is probably chiefly excrementitious, and, like the urine, is constantly being formed and cast out. (2) Though the bile probably assists in the absorption of fats, its presence in the intestine is not necessary for the digestion of such an amount of fat as is capable of supporting life and keeping up nutrition. (3) Increase in body weight and good health are quite compatible with the entire absence of bile from the intestines. (4) The antiseptic properties of the bile are unimportant. (5) Whatever little antiseptic quality bile may have is probably derived from its admixture with the gall-bladder fluid. (6) The supposed stimulating effect of the bile on the intestinal walls is not necessary for a regular action of the bowels.

Paroxysmal Tachycardia.—J. M. Patton makes a defence of the name and illustrates by clinical examples the difference between the essential and ordinary forms of symptomatic "heart hurry." He finds the morbid anatomy indefinite, but believes myocardial lesions frequently present. The prognosis is unfavorable and the treatment unsatisfactory. The discussion by members of the Chicago Society of Internal Medicine accompanies the paper.

Experimental and Clinical Notes on the Subarachnoid Space.—Dudley Tait and Guido Caglieri give historical data and methods of reaching the subarachnoid space. They maintain the priority of Dr. Leonard Corning in cocaine analgesia by the spinal route. Experiments relating to the diffusion of the cerebrospinal fluid are given, and also the results in man from the injection by the cervical and lumbar routes.

Common but Generally Unrecognized Symptoms of Eye-Strain.—E. G. Starr speaks of other symptoms besides the headaches which are due to eye-strain. Among them are pain in the back of the neck, mental confusion, confusion of ideas, inability to fix the attention without effort, backwardness in children; irritability in adults as well as in children, vertigo, fluctuating character of the handwriting, disturbances of the digestive apparatus, etc.

Review of the Present Status of Jonnesco's Operation.—By Marcel Hartwig.

Case of Perforating Gastric Ulcer.—By Allan Jones.

The Lancet, June 30, 1900.

The Excretion of Urinary Water and Urea from the Human Body with Diminished Kidney Weight.—According to J. B. Nash, the following conclusions appear to be justified: (1) If one kidney be removed, then three years subsequently the healthy kidney *in situ* will excrete more than the average quantity of urinary water produced by two normal kidneys. (2) This same kidney will execrete per cubic centimetre of urine and per diem the average amount of urea that would be produced by two healthy kidneys. (3) If one-half of one kidney be removed, then two years afterward the urine voided will be the same in quantity as if two healthy kidneys were present. (4) The loss of the half of one kidney will cause no increase or diminution in the percentage of total amount of urea execreted. (5) If one kidney be removed, then the quantity of urinary water excreted by the other during the seven weeks immediately succeeding the operation will be below the average daily amount. (6) The urea produced by this one kidney will be less than the average proportion usually seen as the result of the work of two healthy kidneys, but probably not below the average excreted by two healthy kidneys from an individual recovering from a serious operation.

On the Use of Mercury in the Treatment of Cardiac Failure due to Arteriosclerosis.—A. Morison gives the history

of a case in which mercury seemed to subserve a useful purpose, and discusses the effect of the addition of some preparation of this remedy to diuretic combinations in general. He shares the opinion of Broadbent that much importance is to be assigned to its effect in lowering vascular tension. How this is brought about—whether by the elimination from the blood of waste material which has a spastic effect upon the arterioles or by direct dilatation of the peripheral vessels in the process of its own elimination—it is not necessary at present to inquire and is very difficult to determine. That the permeability of peripheral vessels by a lessening of their resistance is secured appears to be clinically demonstrable. This being so it is not difficult to imagine, and is indeed permissible to suppose, that the combination of mercury (a peripheral dilatant) with digitalis and squills (which are in part central stimulants as well as peripheral contractors) constitutes it a rationally indicated adjuvant to the action of the latter in cardiac failure due to arteriosclerosis.

The Primary Disorders of Growth.—H. Gilford concludes a lengthy article by stating that the four primary growth diseases—hypoplasia, hypertrophy, degenerative hypoplasia, and degenerative hyperplasia—are all represented in the skeleton. They form two divisions of which the one—hypoplasia and hypertrophy—is distinguished by mere defect or excess of normal growth; while the other, in which are comprised the two degenerative diseases, shows all those broad clinical and anatomical features which in the first part of his article were seen to be characteristic of the degenerative diseases of growth, whatever the tissue may be that they effect. And as degenerative hypoplasia of the skeleton is seen to run into degenerative hyperplasia by imperceptible gradations, each being distinguished from the other by characters imprinted by age alone, so degenerative hyperplasia is subdivided into two diseases according to tissue. If it affects the hard substance of the skeleton especially, it is called osteitis deformans; if the soft substance, it is called osteomalacia.

A Case of Syphilitic Fibro-Spongioid Osteitis.—J. B. Hall describes the case of a boy aged fourteen years, who presented the lesions suggested by the title. As a result of congenital syphilis there had been an osteitis of the clavicles, lower jaw, the right humerus, and both tibiæ. According to Parrot, states the author, the fibro-spongioid or rachitic form of the disease never appears before the fifth month of life. It begins as a subperiosteal growth of yellowish pearly fibroid material over which the periosteum is much thickened and closely adherent to it. It may attain as much as half an inch in thickness and is very vascular. There is always a distinct line of demarcation between the new tissue and the bone beneath. The bones most commonly affected are the humerus at its lower end, the ulna, the femur, and the tibia. Although two distinct forms are thus described by Parrot, both are usually present together in varying degree, the osteoid tissue being covered by a layer of the fibro-spongioid material.

British Medical Journal, June 30, 1900.

On Lead Encephalopathy and the Use of Diachylon as an Abortifacient.—W. B. Ransom records three cases of cerebral disease due to lead poisoning, two of which were caused by diachylon taken to proeure abortion, and some other cases in which diachylon taken with the same object produced a different set of symptoms. It seems that in England balls of diachylon to sell for a half-penny or penny are kept by druggists, and are commonly purchased for this purpose. The dose represents about 23 gm. of lead. It appears to be a fast-growing evil. The treatment consisted, among other things, of moderate doses of iodide of potassium and Epsom salts.

Note on a Case of Lannelongue's Craniectomy.—Charles Ward relates the case of a presumably syphilitic boy, aged six years, presenting hard, regular, symmetrical thickening of the skull, haziness of the cornea, profound symmetrical deafness, etc., from whose skull strips of bones were removed from either side with marked relief of symptoms. Five months after the operation the boy died suddenly. Down to 1894 Treves reports only thirty-six such operations, with four deaths.

Berliner klinische Wochenschrift, June 18, 1900.

The Effect of White and Dark Meat in Chronic Kidney Disease.—A. Pabst has made a series of experiments with these articles of diet, attention being paid to the amount, specific gravity, albuminous contents, casts in the urine, and the general condition of the patient. The results as tabulated are conflicting and variable, but in a general way it may be said that they show that dark meat increases the albumin and diminishes the quantity. In general condition no special change could be noticed. Furthermore it was shown that patients did better on a milk diet than one containing either kind of meat.

The Value of Courmont's Serum Reaction in the Early Diagnosis of Tuberculosis.—Beck and Rabinowitsch have made a large number of observations on the agglutinating power of the serum of tuberculous subjects on cultures of tubercle bacilli grown under the conditions described by Courmont. The blood of seventy-three individuals was investigated, and as the results of their observations the authors are forced to admit that the new procedure is not likely to be of practical value in diagnosis. On the one hand, in cases of beginning tuberculosis only in comparatively few instances did the serum exhibit its agglutinating properties, while on the other a relatively large number of patients in advanced stages of the disease, and who, according to Courmont, should in general not give the reaction, possessed a very high agglutinating index. In addition it was observed that the blood serum of a large number of non-tuberculous individuals had the property of agglutinating the tubercle bacilli, while others distinctly in the earlier stages of tuberculous disease, some of them responding unmistakably to tuberculin, gave an absolutely negative result. In consequence the inference is made that the Courmont serum reaction is not specific for tuberculosis, occurring in non-tuberculous human beings and animals, and often being absent in true tuberculous cases, and therefore is not to be regarded as of any significance in arriving at a diagnosis.

The Relations of Mosquitos to the Malarial Parasites in Kameroon.—Ziemann has for over a year been collecting evidence bearing on the mosquito theory of the propagation of malaria. After a laborious search which included the investigation and sectioning of hundreds of individuals of thirteen different species of mosquitos, a variety of Anopheles was finally found which gave positive results. Thirty per cent. of the mosquitos of this species caught in a certain malaria-infected locality contained in their stomachs malaria coccidia of various degrees of development and corresponding closely to those described by the Italian investigators. Experiment with insects cultivated from larvæ gave negative results, but the same insects, after sucking blood containing malarial crescents, became infected. Anopheles which had not imbibed any of the crescent forms, but had obtained only the blood, never developed the coccidia. Although the author's material is still small, he considers it of importance to have shown that in Kameroon, as elsewhere, the parasite of febris tropica is metamorphosed into a coccidia-like body in whose interior the so-called sporozoites subsequently develop, and which takes the mosquito as host.

Observations on Some Rhinological Instruments.—By Jaenicke.

Fourth Report of the Malaria Expedition.—By R. Koch.

American Journal of the Medical Sciences, July, 1900.

Notes on Diabetes.—J. B. Herrick speaks of casts found in large numbers in the urine during or just preceding diabetic coma. If urine obtained as coma approaches be

allowed to stand for a few hours, a light, hazy, grayish or slightly yellowish sediment will be seen at the bottom, consisting almost entirely of short, broad, light-colored, finely granular casts. There is no relation between the amount of albumin and the number of casts found. The casts may occur twenty-four hours in advance of the coma, and thus give warning. He next speaks of the occasional low specific gravity of saccharine diabetic urine, being lowered below the average of saccharine urine or even that of normal urine. The only safe plan is to examine for sugar, no matter what the specific gravity. This is of importance to life-insurance examiners.

A Case of Dermoid Cyst of the Mediastinum.—F. S. Mandlebaum gives a pathological account and history of a case of dermoid cyst seen at the Mt. Sinai Hospital in 1898. Cysts of the mediastinum are rare. Eleven of Hare's five hundred and twenty cases of mediastinal tumors were dermoid cysts. Hoffman found but fourteen cases recorded. He divides them into true dermoids, those containing cartilage and cylindrical cells, and those combined with lymphoid tumor. The author's collected cases, including his own, brings the number up to thirty-seven. He thinks certain tumors should be classed with the teratomata, and suggests the following division: (1) True dermoids containing only ectodermal structures; (2) teratoma or those with structures from the entoderm and mesoderm; (3) teratomata with the addition of tumor formation.

Pneumonic Complications in Pulmonary Phthisis.—W. Ophüls has examined the lungs of fifty-six phthisical patients with regard to pneumonic complications, and among thirty-seven successive cases he found them in twenty-five instances. He is able to confirm the statement first made by Orth that there is one form of pneumonic process met with in tuberculous lungs which seems to be produced by a simple infection with tubercle bacilli. Among sixteen cases of mixed infection there were nine of acute bronchopneumonia without caseation; four with apparently rapid and extensive caseation, and four with carnification. There is much to be attributed to mixed and secondary infections in the development of the destructive process in phthisical lungs.

Carbolic Gangrene.—F. B. Harrington reports eighteen cases of gangrene of the fingers resulting from weak carbolic dressings. These added to those found recorded in various countries make a total of one hundred and thirty-two cases, and it is assumed that many hundreds have never been made public. Carbolic acid in any strength as a moist dressing is dangerous and ought never to be used. This needless destruction of fingers should be stopped by including carbolic acid in the list of drugs obtainable only on physician's prescription, and having it always labelled as dangerous.

Clinical Study of Ocular Symptoms Found in So-called Posterior Spinal Sclerosis.—C. A. Oliver says that according to the newest teachings so-called posterior spinal sclerosis is a disease dependent upon an atrophy or degeneration of the sensory neurons, followed by sclerosis, though most probably antedated by varying degrees of low-grade inflammation. He makes broad generalizations of the ocular symptomatology of this affection from studies extending over more than five years.

Irritable Bladder in Women.—Richard Knorr calls attention to the fact that more modern methods of examination have done much to clear up the etiology of the various bladder symptoms so common in women, and that especially the diagnosis of "neurosis" of the bladder is to be made with the greatest caution. The careful use of the cystoscope will in nearly every instance reveal the presence of some organic lesion, and also make possible local applications to the seat of the trouble. Thus, out of sixty-three cases studied by him, in only seven were the indications present in the urine itself such as to point toward disease of the uropoetic mucous membrane, and without a local examination the trouble would doubtless have been ascribed to hysteria. The most common cause is chronic cystitis of the vesical neck, which was present in nearly one-half of the above-mentioned series. Complicating this, or as distinct etiological factors, are ulcerations or papillomatous growths of the bladder wall, chronic urethritis, pericystitis, and, dependent on this latter, distortions or displacements of the bladder due to peritoneal adhesions. Fissure of the internal sphincter, hyperæmia, or phlebectasis of the trigonum, malignant disease, subacute catarrhal cystitis, thickenings and sacculations of the bladder wall are all lesions readily seen with the cystoscope and capable of producing severe vesical symptoms. Aside from the purely operative measures required, from the gynæcological standpoint the treatment is simple. Cystitis colli is treated with one-quarter to one-per-cent. silver-nitrate injections; urotropin, oil of sandal, and boric acid internally clear up the cloudy urine; pericystitis yields to repeated dilatations of the bladder with boric-acid solution.

The Origin of Placental Cysts.—De Jong gives a résumé of the literature on this subject and cites the following conclusions: The cysts may be situated (1) in the amnion; (2) in the omphalo-mesenteric duct; (3) in the chorion on its fœtal surface or in the membrana intermedia of Hunter. They may be due to: (1) Malformations of the amniotic folds; (2) persistence of the omphalo-mesenteric duct; (3) stagnation of its contents; (4) malformation of the chorionic villi; (5) local myxomatous formations; (6) infarcts or hemorrhages. His own observations lead him to conclude that: (1) placental cysts occur either singly or in groups and varying in size from microscopic dimensions to a diameter of from 9 to 10 cm. (2) They are situated on the fœtal side of the placenta and are most often found in the basal portion of the chorion. (3) They are due to malformations of parts of the chorionic villi which become adherent through the fibrin secreted by the cells of Langhans. (4) Their inner surface is lined with the cells of Langhans, which may show overgrowth or degeneration. (5) Their contents consist of detritus from the cells of Langhans, the secretion of the same cells, and also blood fibrin and coagula. (6) They are not the results of a local or general disease, and themselves do not occasion any disturbances of clinical interest.

Massage in the Treatment of Tubal Diseases.—Richard Palm enters a vigorous protest against hasty operative interference in every case of tubal disease, and strongly recommends massage as a most valuable conservative measure. Properly and carefully carried out it is free from danger and may be practised even during pregnancy without causing any mischief. Tumors known to be formed by a hydrosalpinx may be very advantageously treated in this way; the effort should be made to cause the fluid to empty itself into the uterus, from which it drains without risk of sequelæ; care should be taken not to exert pressure near the fimbriated extremity of the tube, though even expression of the contents of a hydrosalpinx into the abdominal cavity need not occasion alarm. In cases in which the fluid is known to be purulent an interval of three months is sufficient to insure its sterility. The author reports a case of cyst of doubtful location and nature which, after prolonged massage treatment, was purposely ruptured. No bad results followed, and under continued massage the fluid was completely absorbed and a cure was effected.

Revue de Chirurgie, June, 1900.

Intermittent Fibrous Polyps of the Rectum.—Maurice Péraire says that although rectal polyps and polypoid growths are frequent enough in children, in adults tumors of this sort are comparatively rare, and furthermore differ from the former in being hard and fibrous, instead of soft and mucous as is the case in younger patients. After an exhaustive résumé of the literature on the subject he divides the tumors pathologically into: (1) mucous polyps; (2) fleshy, sarcomatous, or vascular polyps; (3) polyps due to hypertrophy of the intestinal follicles; (4) fibrous polyps —(*a*) the true fibrous polyp growing from the submucous tissue, (*b*) the fibroid of the rectum. This is analogous to the uterine fibroid and develops in the recto-vaginal septum or in the thickness of the intestinal wall itself. A peculiarity of the symptomatology is that the patients usually do not seek professional advice until the tumor has attained considerable size, though close questioning reveals the fact that for several years they have been suffering from a sensation of weight in the rectum, obstinate constipation, tenesmus, and bloody defecations. Characteristic symptoms are the grooving of the fecal masses in their passage over the tumor, and if it be placed low enough down in the rectum the intermittent appearance of the growth after defecation and requiring manual reposition. Of the complications the most important is the general debility which often results from the repeated hemorrhages; strangulation is not common, though prolapse of the rectal mucous membrane is not infrequent, especially in children. The treatment in all cases consists in extirpation. When the growth is accessible from the anus, the most satisfactory method consists in exposing the pedicle of the tumor by a V-shaped incision, and then ablating it after ligating it either *en masse* or in sections. In those cases in which the tumor is out of reach or involves the

entire rectal wall, and invasion of the perirectal tissues is necessary, accordingly as the tumor is anterior or posterior laparotomy or resection of the sacrum after Kraske is indicated.

Chronic Proliferating Osteomyelitis.—Kozlovsky, under this title, considers a form of bone affection often diagnosticated and treated as sarcoma. The clinical picture does not vary essentially from that of a malignant new growth, but on aspiration the fluid obtained is found to be rich in staphylococci, especially the staphylococcus pyogenes aureus. The reason why the same organism should sometimes produce a typical acute osteomyelitis and sometimes under apparently similar conditions cause this puzzling sarcoma-like new growth, is hard to find; the most logical explanation seems to be that of Kocher, who refers it to variations in bacterial virulence and tissue reaction. If the conditions are unfavorable for the growth of the staphylococcus, and its vitality is not great, there will be produced an obscure symptom complex commonly classed among the manifestations of "subacute rheumatism"; if the activity of the germs, however, is somewhat greater and phagocytosis in consequence more energetic, there will result foci of necrosis surrounded by areas of reactionary inflammation, vascular and actively proliferating, and giving the physical signs of a sarcoma from which also the diagnosis can be made only when the microscopical examination is supplemented by a bacteriological investigation.

Endotheliomata of the Bones.—Thévenot has collected from the literature fifteen cases of endothelioma of the bones, and discusses their morphological and clinical features. Most of these had been diagnosticated as sarcomata or aneurisms of bone, and even microscopically the distinction is a difficult one to make. Characteristic points are the disposition of the cellular elements about the vessels either directly in contact with the blood or separated from it by an endothelial layer; the regular form of the cells without budding nuclei, and the absence of cells having multiple nuclei. The new growth is found in patients of all ages; sex apparently is also without influence. No cause can be assigned, though trauma seems to act by producing a locus minoris resistentiæ which undergoes a secondary degeneration. The history of the growths is essentially that of malignancy. Left to themselves they conquer the patient as quickly as sarcomata. The clinical diagnosis is extremely difficult, and the treatment is that for all malignant growths, though in suitable cases a tentative conservative operation is permissible.

Compression of the Pedicle of a Movable Kidney by a Distended Gall Bladder.—By E. Reymond.

Cancer of the Large Intestine Excepting the Rectum.—By R. De Bovis.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE REBELLION OF THE ROYAL COLLEGES—BRIBERY IN ASYLUMS FOR LUNATICS—THE WORLD'S TEMPERANCE CONGRESS—HOSPITAL SUNDAY FUND—MISMANAGEMENT AT THE HOSPITAL FOR PARALYSIS AND EPILEPSY—TYPHOID INOCULATION—JENNER INSTITUTE.

LONDON, June 22, 1900.

THE two London colleges have adhered to their determination to defy the Medical Council, and now proceed to deny the existence of any sovereignty. The diplomatic document announcing this was presented at the last meeting of the Council, when it could not be considered, and so active hostilities are postponed until the next session. The document is not easy of access, being marked "confidential," as too many of the Council's printed matters are. But a glimpse at the one in question shows that the colleges are cognizant of the possibility of the course I indicated, for they assert that the Council's action is "outside its powers," and then proceed to declare that the attempt to enforce its decision by "refusing registration to students of those schools" it has not approved "would have no justification." If the colleges mean that they would not consider this course justifiable, they are welcome to their opinion. But that the course would be legal is clear enough, and that all unprejudiced persons would consider it justifiable is certainly the general conviction. But the rebellious colleges are determined, if possible, to obtain complete independence. They declare that "the whole of the structure of regulations and requirements which the Council has erected on the same groundless assumption of authority are invalid as such, and can only be received for what they are worth as recommendations."

Often have I smiled at the Council *recommending* what it should have *required*, and this is the reward of its weakness. But the colleges had better beware. It is a very simple procedure to refuse to register any student who has not complied with the requirements, and let the colleges make good their boasting by an appeal to the law. It would be something strange to see the Royal College of Physicians and the Royal College of Surgeons join hands in an attempt to set back the educational clock. To many it would be a revelation of the innate selfishness of these colleges. But they will not dare—for though they might defy the Council if it were the interest of the other corporations to do so, just the opposite is the case. These two colleges want to steal a march on the others for their own profit. It is hardly in corporate nature to help to transfer the corporation profits to the coffers of a rival.

Great indignation is being expressed at a system of bribery which has just been exposed by a committee of the St. Pancras Guardians. A report of this committee shows that the relieving officers received money from licensed lunatic asylums for giving them the preference. These asylums charged the board two guineas a week for a patient, while other parishes only paid 19*s.* 3*d.*, so there was ample room for bribery. This system of bribery of officials seems to have secured nearly all the pauper lunatics of St. Pancras—the amount paid to the two asylums reaching over £12,000 a year. It is the old story of improper commissions defrauding the public, and seems to have been going on for many years with the St. Pancras relieving-officers. It is well that the fraud has at last been detected, for St. Pancras is not the only parish in which it has flourished. A few months ago there was an allegation against Bethnal Green, and I heard that a local government board inquiry was made, but the result has not been made public. Perhaps now the board may awake from its sleep.

I regret to say that some doctors have been weak enough to connive at the commission system by giving the odd shilling of their guinea for certifying a lunacy case to the officer who brought it—some indeed outbid their neighbors and gave half-a-crown or five shillings. Of course the doctors who stood on their dignity and refused to give presents seldom had a case brought for certification. It is to be hoped the exposure of the system will prove effectual to prevent its recurrence.

The World's Temperance Congress has been held at the Examination Hall of the Royal Colleges. A thousand delegates assembled from various countries, and about half of them attended a preliminary meeting to welcome the veterans who were present at the convention of 1846. The Archbishop of Canterbury was president of the Congress and delivered a spirited address. The only country that sent delegates in 1846 was America, and those who took part in that meeting scarcely could have anticipated the world-wide character of its successor. The scientific and medical aspects of the question were well represented.

In connection with this may be named the Medical Temperance Association's annual meeting on the 12th inst., when the president, Dr. Sims Woodhead, gave a reception to the medical and scientific delegates to the congress. A demonstration with the electric lantern was given in the lecture theatre by Dr. Ridge, showing that minute quantities of alcohol interfered with the growth of both vegetable and animal cells and delayed oxidation. The removal of waste products was thereby hindered and other functions were interfered with.

On Sunday sermons were preached on the temperance question in most of the London places of worship and in many of those in the provinces.

This reminds me that next Sunday is the metropolitan Hospital Sunday, when sermons will be preached on behalf of the hospitals and collections made. *The Lancet* has again distributed a special supplement teeming with facts which will be useful to ministers preparing their appeals. There is naturally some misgiving lest the demands on public generosity made by the war funds should cause a diminution in the collection for hospitals. And yet this should not be, for the hospital donations should be regarded as regular annual subscriptions, for the poor and sick are always with us; while the war contributions may happily be looked upon as exceptional calls on the patriotism and generosity of the nation.

Last year the Hospital Sunday Fund amounted to above £53,000, but some £15,000 of this came from donations leaving £38,000 only to represent the collection of small amounts. This is less than 2½ pence per head of the population—a fact which ought to stimulate the working-classes to rush in with their pence to make up for the class above which gives fewer shillings than might be expected.

The National Hospital for the Paralyzed and Epileptic is so identified with good work that you may fancy its management is a model. This, however, is not the case. The good work is that of the medical staff. But the board of managers seem unconscious of their own insignificance, and trouble has for some time been brewing. The staff

have at last been goaded into stating that the administration of the hospital is "unsatisfactory." This is a very serious step, and unless the board takes the advice of the staff the success of the hospital will be imperilled. I have for some time been aware of blots on the management, and now the staff has moved hope for reform. The sooner the board makes peace with the staff the better will it be for the institution.

The large number of typhoid cases among our troops in South Africa is naturally a cause of anxiety lest the hope of success for antityphoid inoculation should end in disappointment. A great number of officers and men submitted to inoculation in hope of preventing attacks of the disease, but so far as can be gathered no case for immunity has been made out. In fact the figures rather point the other way. It may be that when the statistics are more complete a more favorable result will appear, but for the present we can only hope it may be so, and the hope grows fainter.

The Jenner Institute has been unsuccessful in its attempt to escape paying rates as an institution for the promotion of science. The judge regarded its object as the preparation and sale of medicines. This seems rather hard lines on its effort to supply the profession with reliable serum, which it does at a loss instead of a profit.

NEGROES IN THE MEXICAN REPUBLIC.

To the Editor of the Medical Record.

Sir: An article on the American negro in a recent issue of the Medical Record led me to examine into the condition of the Mexican negro, and I send you herewith the results of my inquiries. Bishop Bartolomé de las Casas, seeing the pitiable treatment the Mexican Indian was subjected to by the Spaniards, and moved to compassion, brought about the introduction of the African negro, whom he considered an inferior being and better fitted for hard work in the mines. Slavery, not only of the negro but of the Indian likewise, existed in Mexico until 1813, when the first national congress, at Chilpancingo, on a motion made by the Priest-General Morelos, abolished slavery forever.

In no one of the Spanish-American countries was there ever to be found proportionally so large a number of negroes as in the southern States of the United States. It is to be noted that the negro is much less reproductive than the Mexican Indian. It is utterly impossible to give even an approximate estimate of the number of black people in Mexico. According to a census taken in 1835 there were then six thousand negroes in the republic. I have not found in any other census any data with regard to the number of inhabitants of African descent. In fact, any black man, if asked his race, will hardly call himself a negro, but will hold himself to be of dark complexion. Yet in an old book by an Englishman, who travelled in Mexico some one hundred and twenty years ago, I have read that then in the City of Mexico there was such a great number of negroes (over forty thousand) that they were considered a dangerous factor.

I estimate, however, that in this country there live over ten thousand negroes and numberless individuals in whose veins some African blood flows. Those negroes live mostly in the state of Vera Cruz, in the south of the state of Morelos, and in Guerrero. They enjoy perfectly equal rights with the white man and the Indian, not only by law, but practically. No man is slighted because his skin is black; every career is open to him. We have seen black generals (that does not mean much), black lawyers, congressmen, professional musicians. I confess never to have met with a negro doctor or priest. Yet there is no doubt that a black boy would be admitted to either profession if he wished.

The negro in Mexico lived in general under a milder rule than in the North, and after the abolition of slavery he was not treated or regarded as an outcast and an inferior being. All the negroes in this country are farmers, many of them well off. One hardly ever sees a negro girl serving as a domestic, or a negro craftsman in a workshop. Their number increases, though more slowly than that of the Indians, as they are less prolific. They are somewhat industrious and not remarkably immoral. No case of fetishism or cannibalism among them has been known. Their social condition improves visibly.

When slavery was abolished in Mexico, the negro was certainly not better prepared for freedom than he was in the southern States. Consequently, if we try to find a reason for the difference in their development and for the different use they made of their liberty, we must look for it elsewhere than in the sudden transition from slavery to liberty and their unpreparedness for freedom. There must be some other cause for the different development of the same element in two different countries and under much the same circumstances. May it not have been of the greatest moral effect that in this country the negro, from the day he was freed, was held to be a man and a citizen and anybody's equal?

Sir Spenser St. John, who had lived as British minister in Hayti and later on in Mexico, in his book on Hayti gives a most pitiable description of the blacks of that island, who fell back into all the horrors of savagery of their native Africa, into a condition toward which, according to some American authorities, the North American negro is drifting.

It might be used as an argument against the black race, that in Hayti nobody interfered with the development of the negroes, and that their actual condition in Hayti is only their natural one. But I wish the friendly reader to consider that the negro of Hayti obtained his liberty only after a cruel and bloody struggle which quickened all his atavistic instincts, and that the civilizing influence and example of the white man were completely withdrawn from him.

F. Semeleder, M.D.

Cordoba, V. C., Mexico.

THE ALLEGED BREEDING OF TAILLESS MICE THROUGH THE INHERITANCE OF MUTILATIONS.

To the Editor of the Medical Record.

Sir: There is not a more important question in theoretical medicine than the one which at present absorbs so much of the time of our biologists, whether modifications acquired by an organism, and not inherited as a normal variation, can be transmitted to its offspring. Physicians, as a class, are so thoroughly convinced that acquired modifications are transmitted in family lines, that to ask them to give up their belief is almost as futile as to ask them to renounce their faith in a future existence. Nevertheless Weismann has shown that there is not a single unchallenged instance of the transmission of an acquired modification, and his teachings are apparently being accepted by the younger generation of biologists, just as Darwin's theories were accepted by the younger men of a generation ago. It is interesting to note that all the facts of organic evolution, though first explained by Lamarck on the theory that certain individuals became modified by their environment and thus originated new species by transmitting these modifications to offspring, are now wholly explained by the survival of congenital variations making the possessors better fitted to the environment than were the parents. Darwin believed in both processes, yet as he grew older he confessed that he saw less and less evidence of the transmission of certain alleged acquired modifications. The common mistake among physicians is the failure to recognize that their instances are not the transmission of acquired modifications, but are really variations in development which are strictly transmissible in varying degrees. The character which the child possesses in an excessive form may not have been acquired by the parents at all, but have existed from birth.

Telegony, or the influence of one father upon subsequent pregnancies by other males, has always been a stumbling-block. But now comes the almost certain proof[1] that there are absolutely no instances of this alleged fact, and in hundreds of experiments of breeding an animal to a male of a different variety, and in subsequent years breeding her to a male of her own variety, these later offspring are always pure. Weismann also shows that there are no reliable instances of telegony.

Mutilations were long ago resorted to for proof of the transmission of acquired modifications, and although mutilations are not the modifications usually thought of as better fitting an organism to its environment, yet it was seen that if such gross changes could be transmitted, surely the more subtle ones could be. In only one case has there been a report of the successful transmission of mutilations,[2] and it has been so extensively quoted that I have taken the trouble to trace the fake down, thought it has taken nearly three years to do so. It was alleged that tailless mice had been bred by cutting off the tails of the young as soon as they were born, and in six or eight generations tailless litters were born.

Dr. Charles E. Lockwood, of New York, is generally referred to as the experimenter, but he writes me that he had nothing to do with it except as below mentioned. In discussing the subject of the transmission of mutilations with Col. S. D. Bruce, editor of *Turf, Field, and Farm*, the latter referred to a Mr. A. S. Shiddell, of Lexington, Ky., who had thus bred tailless mice. They wrote to Mr. Shiddell, who kindly detailed the experiments, and his letter was given to Prof. H. F. Osborn, who quoted the follow-

[1] Popular Science Monthly, June, 1900.

[2] Medical Record, May 14, 1892.

ing extract in his Cartwright lecture: "I selected a pair of white mice on account of their rapid breeding. I bred them in and in for ninety-six generations, as they breed every thirty days, and when they are thirty days old they are able to reproduce themselves. I destroyed all sickly and defective ones by breeding only the fittest. I bred all disease out of them, and had a pure-blooded animal, larger and finer every way than the original pair. In breeding their tails off, I selected a pair and put them in a cage by themselves, and when they had young I took the young and clipped their tails off. When old enough to breed I selected a pair from the young and bred them together, and when they had young I clipped their tails. I continued this breeding in and in, clipping each generation, and selecting a pair of the last young each time. In seven generations some of the young came without tails until I got a perfect breed of tailless mice. I then took one with a tail and one without a tail and bred them together, and by changing the sexes each time—a male without a tail and a male with a tail—I was finally rewarded with all-tail mice." Professor Osborn said: "There is such general scepticism now in regard to the inheritance of mutilations that it will be necessary to repeat these experiments in some well-known physiological laboratory. As told above, they seem to be perfectly trustworthy, but facts which go against a theory must be doubly attested."

Mr. Shiddell, in a letter to me, says that he was ten years at this work, yet by his own statement not more than six generations can be obtained in one year, so that his ninety-six generations would take sixteen years alone for the preliminary experiments before he began the tail clipping. It is absurd to suppose that a man would take such a long time for the preliminary work. In another letter he states that it was only ninety generations, but as the handwriting is not that of an old man but rather that of a young woman, we presume that there is an error in copying. I have been unable to find the length of gestation in white mice, but as they are merely albinos of the common house mouse, we presume that they have the same period—twenty-seven days, and are not developed until three months old. This would limit them to three generations a year, and for the whole length of Shiddell's experiments a period of thirty-three years is necessary. It is not likely that in-and-in breeding for ninety-six generations will result in finer specimens than the original, nor will it breed all disease out of them. We are taught to believe the reverse.

He states that he got some tailless ones in seven generations, but does not state how much longer it took to get them all tailless. In a letter to me, he says that in the sixth generation some came tailless, and "in the seventh generation all came without tails and they continued coming without tails." In a letter to Dr. Lockwood he states that he had no time to make other experiments, yet the above letter claims to have reversed the process.

It is interesting to note that while Shiddell succeeded in seven generations, Weismann failed in identical experiments after nineteen generations, that Retzema Bos and Rosenthal failed both with rats and mice,[1] and that Dr. S. M. Worthington[2] calls attention to the utter failure of such mutilations to be transmitted in the dehorning of cattle, and clipping the ears of hogs and the tails of lambs.

Shiddell gives the following as his reasons for attempting the experiments: "Quite a number of years ago, I wished to carry out a theory of mine, which was that each particular part of the animal organization furnished the substance to reproduce that part, this being entirely original with me, never having heard of any experiments being made"—(Darwin's pangenesis).

The cause of this remarkable publication of imaginary experiments is found in Mr. Shiddell's mental equipment. He is evidently well known locally, as shown by the following extract from a letter sent to me by the editor of *The Kentucky Gazette*, of Lexington: "He is a gentleman who for a long time conducted a small grocery, and was known as a sort of amateur with flowers, white rabbits, etc. He must be about seventy years of age, always bore a good reputation, and as far as we know bore a name unsullied by falsehood. We know nothing of his raising white mice, but it is like him to do so, and if he undertook such a vocation he would watch it closely."

As Mr. Shiddell claims to have been personally known for over forty years to Colonel Bruce, we can well believe his reputation for eminent respectability. His real personality was not known to either of the above gentlemen. I learn from Dr. S. M. Worthington, of Versailles, Ky., that some of his friends who have seen Shiddell have informed him that Shiddell is not reliable. He is evidently a gentle, dear old soul, of visionary nature, full of strange conceits, who had thought so much of his theory of pangenesis that he finally brought himself to believe that he had actually made the experiments which he describes with so much irreconcilable detail. Deliberate falsehood or practical joking is quite out of the question in such a case.

It is highly important that the real facts be known, for the alleged experiments have been published far and wide as attested scientific facts. Dr. R. Harcourt Anderson refers to them in the MEDICAL RECORD of October 2, 1897; Dr. E. S. Talbot quotes them in his book on "Degeneracy"; an editorial in the *Journal of the American Medical Association*, November 18, 1899, accepts as a fact that mutilations are transmissible, and Dr. Lockwood informs me that he has received so many letters of inquiry on the subject that it is evident that the original 1892 report has been universally accepted. It is remarkable that scientists should have been so taken in, and almost amusing that Dr. Talbot, in his work on people of nervous instability, should have been the victim of one of these subjects.

We can rest assured that the only way to breed tailless mice is to select those with the shortest tails and continue the process for untold generations, imitating nature's method of natural selection. The process will be a gradual diminution of the tails to their ultimate extinction; but to suppose for a moment that the tails will suddenly disappear in a whole litter, except as a teratological freak due to causes we know nothing about, is the height of absurdity.

CHARLES E. WOODRUFF, M.D., U.S.A.
FORT RILEY, KANSAS.

P. S.—Since the above was written the following telegram has appeared in the daily papers: "Lexington, Ky., June 30th.—B. N. Shiddell, aged eighty-three years, died here to-day. He was a man of eccentric habits, and was known throughout Kentucky as a man who bred the tails off white mice. He labored for nine years to accomplish this result, during which time he bred ninety-six generations of the prolific animals. He swore that he would not shave until Henry Clay was elected President, and he wore his long beard several feet in length, knotted and massed under his vest to keep it out of the way. Shiddell was born in the house in which he died."

WOMEN MEDICAL GRADUATES IN SWEDEN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I beg to correct the heading of your notice on page 1087, vol. lvii.: "A Woman Medical Graduate in Sweden." There are at least a dozen women medical graduates or practitioners in Sweden, but Miss Stecksen is the first to receive the degree of M.D. Upon the completion of the medical course in Sweden, the graduate receives the degree of medical licentiate, which entitles him to practise. To receive the degree of M.D. an original thesis must be written and publicly defended; if this work is satisfactory to the faculty, the author receives the degree of M.D. Miss Stecksen is the first woman medical graduate to do this, and receives and deserves much praise for her thesis: "A Study in the Etiology of Tumors." The heading of your notice conveys the impression that Miss Stecksen was the first and only woman medical graduate in Sweden, which I beg to correct.

C. FRITHIOF LARSON, M.D.
CRYSTAL FALLS, MICH.

Salicylate of Methyl applied on cotton compress with two parts of oil rapidly diminishes pain in epididymitis.—BETTMANN.

Threatened Abortion.—To decrease irritability of the uterine mucous membrane give iodide of potassium, gr. v. three times a day.—MONTGOMERY.

Ataxia should be treated by compensatory movements. Since innervation of the antagonistic force is at fault, resisting movements should be carried out. It is not the degree of inco-ordination, but the character of the case which should determine prognosis.—BUMM, in Gesell. der Aerzte, Vienna, January 13, 1900.

Thinness.—Physical and cerebral rest, country air, hydrotherapy; fatty meats and fatty food; bread crust, pastry, beans, peas, nuts, sugars, honey; Fowler's solution up to gtt. xv.-xx., graduated. Condiments should be avoided excepting salt, acids, sour fruits, salads, cabbage, coffee, turnips, tea, hot drinks, sour wines, tobacco.—LE ROY, *Gaz. des Hôp.*, February 22d.

Clinical Department.

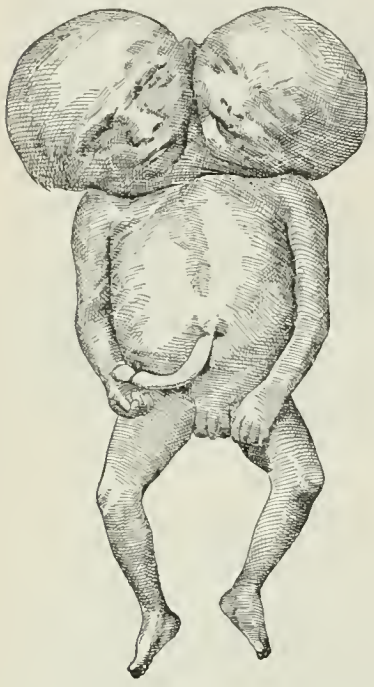
A DIPROSOPUS.

By J. E. CAVEY, M.D.,

WEST ALEXANDRIA, OHIO.

My first case of obstetrics in the new year was of such unusual occurrence that I believe a report of it would be of interest to the profession. It was the spontaneous delivery of a diprosopus.

On January 8th I was called to attend Mrs. H. S——, white, aged thirty-eight years, mother of four children born singly. Her mother had given birth to twins. The child was born dead at about the seventh month of pregnancy and weighed six pounds. I was unable to procure the specimen, but obtained a photograph.



Both heads were of uniform size, the bones of each head being well developed. The features were markedly alike. The body was very well formed. The generative organs resembled those of both sexes, a small but well-defined penis springing from the upper portion of the vulva. Labor was tedious but uncomplicated. The right head rested against the ilium, while the left head escaped from the vulva. The recovery of the woman was uneventful.

A CASE OF EPILEPSY CURED BY OPERATION ON THE NOSE.

By J. J. RICHARDSON, M.D.,

WASHINGTON, D. C.,

DEMONSTRATOR OF RHINOLOGY AND LARYNGOLOGY, GEORGETOWN UNIVERSITY MEDICAL SCHOOL.

Epilepsy is one of the neurotic diseases which we cannot associate with any constant pathological lesion. The exciting cause in individual cases differs widely, and there is no definite or uniform etiological factor demonstrable. The clinical phenomena are usually the same, regardless of the etiology. The nose has many sins to answer for, and among them is epilepsy, as shown by the following case which has come under my care:

Boy, aged twelve years, of neurotic temperament and son of healthy parents with good family history. The boy had been having epileptic seizures very frequently for eighteen months, but much oftener the six months preceding the time he came under my care. Scarcely a day would pass without a paroxysm, and sometimes several would occur in twenty-four hours. The seizures usually were abrupt in their onset, without any apparent aura. There were loss of consciousness, frothing at the mouth, and at times bleeding of the tongue. The symptoms usually quickly subsided, and were followed by a short period of confusion of thought. A rhinoscopic examination revealed a hyperæsthetic nasal passage and a marked hypertrophy of the middle and inferior turbinated bodies of the right nasal cavity. The breathing was obstructed and there was considerable pressure on the septum from the hypertrophied tissue. Under cocaine with the electro-cautery I destroyed the thickened tissue by two operations, one week apart. The month preceding the first operation the boy had not missed a single day without having a "spell," and the week following the first operation he had only three. After the second operation he did not have another paroxysm. He has been under observation eight months and is enjoying perfect health. No other treatment was administered, but he had been taking bromides before the nasal treatment with no apparent effect.

MUMPS IN PNEUMONIA.

By CHARLES W. DULLES, M.D.,

PHILADELPHIA.

It is a curious but well-known fact that at certain times there occurs almost simultaneously a considerable number of cases of forms of disease or injury which are in general quite rare. This has been recently illustrated by the publication by several observers of reports of the development of mumps in the course of pneumonia. The articles in which these cases have been recorded indicate that insufficient mention of this complication, in the text-books, has led to the impression that it is more rare than it actually is. As a matter of fact the occurrence of inflammatory swelling of the salivary glands in the course of pneumonia has been described in really comprehensive works like that of Wilson Fox on "Diseases of the Lungs and Pleura." Still, the publication of recent observations is more likely to put the members of the profession on their guard than its mention in the books. For this reason—and for another—I think it worth while to make public an observation of my own occurring during the past winter, when the other cases were noted. My patient was a woman over eighty years of age, living in the Presbyterian Home for Widows and Single Women, in this city, a person of great neatness and careful habits, who contracted a cold which passed at once into a croupous pneumonia affecting the left lung. She became very ill, but after the crisis she began to improve, and eventually she fully recovered. Just after the crisis I found that she had marked swelling of the right parotid gland, which presented all the characteristics of mumps, and afterward the left parotid gland went through precisely the same stages. In this case there was no question of a second infection from without: it was a plain case of auto-infection.

The second motive for this publication, referred to above, is to describe the treatment adopted. On each side successively I applied a fairly thick compress of surgical gauze saturated with boroglyceride and covered with a layer of paraffin paper and just enough bandage to keep it in place. The relief of pain and the subsidence of swelling which promptly followed the application I am disposed to attribute to the boroglyceride. This is an application of the greatest utility in a variety of inflammatory swellings, and especially in the case of incipient boils and carbuncles. In my hands it has wholly replaced the poultice; and since some years ago, when I began to use it where poultices used to be employed, I have not had to apply the knife to either boil or carbuncle. I have also found it useful in inflammatory swellings below but near to the true skin, and I have observed recently the

extensive advertisement of a nostrum recommended for use in similar cases, which I am informed consists of a mixture of glycerin and talcum powder. If this nostrum proved of value, I believe that it was through the depleting influence of the glycerin; and boro-glyceride—of a strength not greater than fifty per cent.—I presume would be a more rational and equally useful application.

FECUNDITY.

By WILLIAM P. BURKE, M.D.,
NEW HAVEN, CONN.

On the evening of May 23d I was called to attend Mrs. H—— in her fourth labor. After a tedious and rather severe labor I delivered her on the morning of the 24th of triplets, two boys and one girl. The boys weighed eight and nine pounds respectively, and the girl seven pounds, making twenty-four pounds of children in all. There was but one placenta, which was attached in three places, arranged very much like a clover-leaf with membranous connections between the patches of placental tissue.

One of the children, the second, a boy, presented by the feet and died in about fifteen minutes after birth. The others were vertex presentations. On May 1, 1898, I delivered this woman of twins, a boy and girl. She also had previously had two other labors with one child at each birth. Ten months before she gave birth to the twins and about the same time before giving birth to the triplets she miscarried at five months. All of this occurred within six years and one month. Of the seven full-term children but three are living.

Her mother gave birth to eight children in all, and her grandmother to eleven.

A CASE OF SUDDEN AND UNEXPECTED DELIVERY OF TWINS.

By W. C. HANDS, M.D.,
NEW YORK.

Mrs. E. C——, aged twenty-four years, who had previously after a lingering labor given birth to one child, some time ago sent her husband for me. His remarks to me were: "Doctor, mother would like you to stop at the house some time this morning. Emmie [his wife] is not feeling well; there is no hurry, any time will do." By chance I responded at once. Upon arrival at their apartments, I found every one in great excitement, standing about in the most ridiculous attitudes. On the bed, in the knee-hand position, was the patient, naked from the shoulders down. As I entered the room my view of things was a rear-end one, and I saw extending through and from the vulva what proved to be an umbilical cord, dangling from the end of which was a small baby boy. I think my smile was excusable. The patient had been in that position for fifteen or twenty minutes, not daring to move, and no one present had the temerity to render her any assistance. After making her comfortable and delivering the placenta I was surprised to find two cords attached. I mentioned the fact that there must be another child around somewhere, and hunted about the bed without success. Upon questioning the patient as to what room she was in before going to her bedroom, she replied, "The dining-room, but stopped in the bath-room, where the waters broke, and I hurried right in here."

I went into the bath-room, and, sure enough, there in the hopper was the other child, a boy, doing his best to wriggle into a comfortable position. Fortunately, the mother had not pulled the handle, or the child would have gone down, it being an ordinary pan-closet. The patient afterward told me she had pain while in the bath-room and a gush of water, but did not have the slightest idea that anything but the water had passed from her, and when she reached the bed and was about to lie down in it a child dropped from her, and she was afraid to move or lie down. There was absolutely no pain with the delivery of the second child, only the tug when it reached the end of the cord, which did not break as the first one had done. There had been a miscalculation of two months in this case of the probable date of parturition, and the mother had no idea of the cause of the pain, even when the waters broke, until the second child fell from her while stepping on to the bed. Neither child received any injury, and together with the mother both are in fine feather. The parents were intending to name one of the boys William Cornelius, but when they thought of the initials, W. C., it occurred to them that it might be too suggestive of the place where the doctor found him.

205 West One Hundred and Thirtieth Street.

A CASE OF MYXŒDEMA, WITH TREATMENT.

By ETHAN E. GRAY, M.D.,
CHICAGO, ILL.

Mrs. H——, aged fifty-nine years, came to me for treatment of a general "dropsy," which, she stated, had existed for thirteen years, at the beginning of which time the feet began to swell. The œdema, or, rather, swelling, gradually extended upward, and in the fourth year of the disease swelling of the face became apparent. The arms and hands also swelled, and the latter became useless for finer work. The hair, eyebrows, and eyelashes began to fall out, and depilation continued until there were, in January of this year, but a few wisps of dry, split hair left on the scalp.

The headaches became more and more frequent, the mind became obtunded, and reading was abandoned on account of the difficulty of concentration of the mind. The patient became moody, desired to live alone, refusing society, and leading a drowsy existence. She became so somnolent that she slept while engaged in the lighter tasks of housework. The tongue was thick, making speech somewhat indistinct at times. As her thoughts were slow, so was her speech. Her voice became deep, almost masculine in character, and rough. She stated that a sister, near her age, was affected similarly, though in a lesser degree.

The appearance of the patient at the time of my first examination was in thorough accord with the accepted description of Gull's disease: The head was greatly bloated, the scalp nearly hairless; the cheeks were heavy, pendulous, and pale. The ears were thickened, the eyes almost concealed by overhanging water-bags, the lips as thick as a negro's, and the nose was broad and thick. Here and there were patches of rosy color, but the skin as a rule presented a shiny, pale appearance.

The abdomen was enormous, its walls being very thick and imparting a brawny feel to the fingers. The legs were enormously swollen, as were the feet. The thyroid gland was not palpable, the trachea being felt well down toward the base of the neck, through the thickened tissues. Examination of the abdominal organs elicited nothing of note. The spleen and liver were of normal size, but it was impossible to locate the kidneys. The heart was normal.

Uranalysis revealed no albumin, no sugar, no casts.

Urea was excreted in fair quantity; specific gravity, 1.020–1.025. The bowels were constipated.

The patient was at once placed on desiccated thyroids, a hæmatic, and occasional eliminants in the form of the mild chloride. The dose of the thyroids was gr. iii. four times daily at first, later reduced to three times a day. At the end of the third week of thyroid feeding the swelling in the abdomen and in the legs had begun to disappear. In six weeks the patient had taken an interest in household affairs, beginning sewing, reading, and brightening up mentally. The hair began to grow all over the scalp, the eyebrows and eyelashes reappeared. The voice became higher pitched and more feminine in character. The eyelids had become normal in size, while wrinkles appeared over the face. At this date, May 25th, the patient is in a normal condition mentally, and, barring a thick crop of short, dark hair on the scalp, is in no way different from other women of her age.

This case, I think, presents as typical a history of adults' myxœdema as can be desired; and yet, during the thirteen years she has been afflicted, she has undergone much treatment for nephritis and cirrhosis of the liver.

The salient features of the case should not be forgotten, viz., (*a*) the general swelling of the features and of the body; (*b*) the mental condition of the patient, *i.e.*, the disinclination to effort; (*c*) the slow speech and dragging of words. With these points in mind, it should be a simple matter to differentiate between the myxœdematous condition and the dropsies due to renal, hepatic, or cardiac disease.

158 Evanston Avenue.

A CASE OF TUBERCULOUS INTRAPERITONEAL EFFUSION CURED BY INCISION AND PERMANENT DRAINAGE.[1]

By GEORGE I. MILLER, M.D.,

NEW YORK,

LATE HOUSE SURGEON TO BETH ISRAEL HOSPITAL.

O. F——, forty-six years of age, a Hebrew woman, was admitted into the Beth Israel Hospital on August 31, 1897. The family history was negative. She had had the usual diseases of childhood. She began to menstruate when fifteen years of age, and the period was always regular, lasting three to four days, moderate in quantity and painless. She married at the age of twenty-one years; she gave birth to twelve healthy children—her last child being born when she was thirty-five years old. She never aborted. At the age of forty-three, or three years ago, her menstruation ceased.

She always felt strong and healthy up to six months ago, when she was suddenly seized with pains in the stomach and had alternate chills and hot flushes. This condition lasted about a week. Later on she began to notice swelling of the hands and feet. On admission her feet were found to be swollen, and her abdomen was greatly distended with fluid. The heart, lungs, liver, and spleen were examined and found to be normal. The temperature was 99° F. and the pulse 72. Urinary examination was negative; specific gravity, 1.016; no albumin, a trace of phosphates.

Operation: The woman was operated on by Dr. A. Brothers on September 3, 1897, after the usual preparations. An incision three inches in length was made in the linea alba midway between the umbilicus and symphysis pubis. The peritoneum was opened and about three gallons of liquid evacuated. The abdominal and pelvic organs seemed to be normal. The peritoneum was found to be thickened, hyperæmic, and studded with tuberculous nodules. There were slight adhesions in places. The effusion was general, occupying the whole peritoneal cavity. The liquid was slightly turbid, containing some flocculi of lymph. The abdominal cavity was drained with a rubber tube passed deep down into the pelvis and loosely packed with iodoform gauze. This drain was allowed to remain for two months, after which, on October 30, 1897, the patient was discharged from the hospital as improved.

During her stay in the hospital, her highest temperature was 102.6° F., pulse 138; but most of the time her condition in this respect was normal. The wound was dressed every other day. The treatment otherwise was symptomatic.

On May 3, 1900, nearly three years later, the patient presented herself at Dr. Brothers' office. She said that after leaving the hospital she visited relatives in the country with whom she remained a long time. The fluid did not reaccumulate, and she gradually recovered her health and strength so that at present she is perfectly well. No medical or surgical treatment was followed after she left the hospital.

Nearly fifteen years ago the method of draining the peritoneal cavity with tubes after laparotomy was in general vogue, and it is still in use among certain operators, notably W. Gill Wylie and Tuffier. Many years ago Caillé, of this city, published a series of observations in which permanent drainage of the peritoneal cavity in cases of persistent or recurrent effusions (as after cirrhosis of the liver) was resorted to. The method, however, was never apparently generally adopted, the profession preferring to make repeated tappings with trocar and cannula. This case, however, would seem to justify the more extensive employment of this method of permanent drainage in a selected class of cases.

[1] Presented at a meeting of the Eastern Medical Society, held on May 11, 1900.

REPORT OF A CASE OF CARBOLIC-ACID POISONING SUCCESSFULLY TREATED WITH ALCOHOL.[1]

By H. RODMAN, M.D.,

NEW YORK.

As this case admits of no possible doubt in the saving of life by the employment of alcohol in carbolic-acid poisoning, I feel it my duty to report it, and state all details as they occurred.

Although I thought at the time that the particular method I employed was original with me, I have since learned that several other patients had been treated, and successfully too, in like manner. It had been fully demonstrated by Drs. Powell and Phelps that alcohol was a direct antidote to carbolic acid. Powell himself, in front of his class, filled his mouth with pure carbolic acid and allowed it to remain thirty seconds; he then filled his mouth with pure alcohol, and suffered no bad results whatever. We all know its efficacy in the treatment of sinuses, and various experiments have been made proving the direct action of alcohol on the escharotic and destructive action of carbolic acid. It was then suggested that alcohol could and should be employed when carbolic acid has been taken into the stomach. It may seem heroic treatment to pour pure alcohol into the stomach and then wash out the organ, but we know that carbolic acid is one of the most deadly poisons, particularly when large quantities have been swallowed, and that almost every such case terminates fatally.

The treatment of carbolic-acid poisoning up to the present time has been most unsatisfactory, and when

[1] Read at the regular meeting of the Harlem Medical Association on March 12, 1900.

one considers how common a poison it is, and how readily obtained by a layman, we can congratulate ourselves on the discovery of so valuable an antidote. When carbolic acid has been allowed to remain for any considerable time, and when the destruction of tissue has been extensive, alcohol cannot exert much influence on the tissues, but it should, nevertheless, be employed.

My case is as follows: On December 17, 1899, I was called to attend a woman, Mrs. M——, of this city, who had taken poison by mistake. When I arrived in a very short time, I found the patient, sixty years of age, lying prostrate in bed, with a two-ounce bottle of pure carbolic acid on the dresser, and entirely empty. The fact of it being pure carbolic acid was evident, both from the label and after testing it personally, and from the patient's own statement subsequently. I had been told by her son that his mother had been suffering with neuralgia, and had been in the habit of taking medicines; that she had bought pure carbolic acid the night previous for disinfecting purposes, and had placed it on the dresser with the other bottles; that, being seized with severe pains, she poured out the contents of this bottle into a wine-glass and drank it. She soon realized her mistake, calling to her son, who ran around for me. By the time I reached her she was completely unconscious; her pulse was thready and scarcely perceptible; there was extreme dyspnœa, the face was congested, the lips were cyanotic, and the conjunctival and pupillary reflexes were absent. Her extremities were limp and cold. The temperature per rectum was 96.2° F. The patient was in an extreme condition of collapse. An eschar had already formed on her lips and tongue. I gave a very bad prognosis, expecting that the patient would surely die. Of course she could not swallow, so I introduced a stomach tube carefully into the pharynx, not into the stomach, and poured down four ounces of pure alcohol, which I had in my satchel. I allowed this to remain two or three minutes, considering that sufficient time first to exert its antidotal action, and then introduced the tube into the stomach, and washed out the contents with warm water. I then washed out the stomach again with diluted alcohol which I had ordered, and then withdrew my stomach tube. Nothing else had been done up to this point. A second physician, who had been called, pronounced the case hopeless, and criticised my treatment. An ambulance surgeon, who was also summoned, said the patient would surely die, and that it was useless to take her to the hospital. I had noticed some improvement already, and considered the patient strong enough to be removed to the hospital, not knowing what complications would ensue, and that even should the patient rally, I did not think that she could be treated properly at home under the circumstances. The family refused to do this, and I left the house, the other physician remaining in charge. In twenty minutes I was recalled, my colleague having left after telling the people that the patient would not recover. When I returned, I found the patient with consciousness returning, her eyes wide open, begging for cold water. Her pulse had improved considerably, her breathing had become less frequent, and her appearance less cyanotic. She vomited a little and her bowels moved twice, but no blood passed. I then administered strychnine hypodermically and other cardiac stimulants, and employed the usual methods for combating shock. I must not neglect to say that I injected whiskey hypodermically at frequent intervals. Whether alcohol introduced this way combines chemically with the carbolic acid already absorbed, or not, has not been sufficiently demonstrated. Within an hour and a half I had the pleasure of seeing my patient in a cheerful mood, with some mental excitement, probably as a result of the alcohol absorbed. No epigastric pain or abdominal tenderness was present, either at that time or at any subsequent period. With the exception of pain in the naso-pharynx, which I had neglected to spray with alcohol, she was free not only from pain but also from any discomfort whatever. The patient rallied completely, and made an uneventful recovery. On the evening of the same day her temperature was 102° F., pulse 110, but of good quality. She swallowed with slight difficulty. Her urine, which had to be drawn off with a catheter, was brownish-black, of sufficient quantity, and contained no albumin. I ordered Epsom salts to be given regularly every four hours and mucilaginous drinks constantly. She passed a comfortable night. Next day the temperature was 101° F., pulse 100; the urine still much discolored; there was slight pain in swallowing, obviated by cocaine spray. On the third day the temperature and pulse were normal, and the urine was also normal. On the fifth day the patient required no further attention, and I discharged her as perfectly cured. She has had no bad symptoms whatever since. Three weeks after she called at my office, and said she was in excellent health and never felt better. Two months later she suffered from a severe attack of lobar pneumonia following influenza, from which she has fully recovered.

I believe from the foregoing history there is only one conclusion possible. Here was a patient who had swallowed a large quantity of pure carbolic acid, about which there is no doubt whatever. Nothing had been given to the patient previous to my arrival, and she was nigh moribund when I saw her. The carbolic acid had already produced its destructive action, and simply washing out the stomach would have been of little value. We know at least that even if such patients should recover from the shock, the after-effects are most serious, such as gastric and intestinal ulceration, with severe epigastric and abdominal cramps, purging, with bloody stools, vomiting, etc. All of these symptoms were absent, no complications whatever resulting. We had been taught that soluble sulphates were an antidote to carbolic acid, but it has been proven that carbolic acid by mere contact with soluble sulphates cannot unite chemically to form sulpho-carbolates. The scope of this paper will not allow me to go into full details on the complete action of sodium sulphate, but I am sure any physician can demonstrate it to his own satisfaction. That they do combine with carbolic acid to form sulpho-carbolates we know by the examination of the urine, but this formation takes place after absorption in the body. Sodium sulphate certainly would be of little value in saving the œsophagus, stomach, etc., from the rapid destructive action of carbolic acid, which alcohol certainly does. I did employ soluble sulphate, but after the patient had rallied, and to combine with carbolic acid already absorbed, as I considered that rational.

The advantages of this method of employing alcohol are many. The disadvantages are few. One possible disadvantage may be the introduction of a stomach tube, but this is more than balanced by the fatality of the drug when the patient is left alone, and most authorities of the present day advise washing out the stomach in all poison cases. If the tube is introduced carefully and intelligently the danger is very slight. The steps should be in the following order: (1) Introduction of alcohol; (2) washing out the stomach; (3) use of soluble sulphates.

In conclusion, I must say that although my personal experience is limited to this one case, the evidence is so strong as to the efficacy of alcohol in the saving of life in carbolic-acid poisoning when thus employed, and in the prevention of complications subsequently, that I would not hesitate to employ it in every case.

If I may be permitted to do so, I would also suggest that every ambulance surgeon be provided with pure alcohol to be used in just such an emergency as mentioned here, and which occurs so frequently in this city. Future experiences will, I hope, strengthen the facts related here.

Society Reports.

THE PRACTITIONERS' SOCIETY.

One Hundred and Fifty-sixth Regular Meeting, Held on Friday, May 11, 1900.

A. Alexander Smith, M.D., President, in the Chair.

A Case of Venous Obstruction Complicating Cardiac Disease.—This was presented by Dr. A. Alexander Smith. The patient was a young man aged twenty-three years, a chemist by profession. Seven years ago, while a student and bugler at a military school, he began to suffer from attacks of palpitation of the heart, and a physician whom he consulted advised him to remain quiet. He went home, and soon afterward developed an attack of chorea, from which he recovered after several weeks. A few weeks ago, while engaged at his work, he noticed for the first time that there was a difference in the color and size of his two upper extremities: the left hand and arm were cyanotic in appearance, and the arm was œdematous. Varicosities were also noticed in the left pectoral region. Examination of the heart showed a mitral obstructive murmur. The patient had never suffered from pain or other symptoms than those mentioned. Dr. Smith said he had been induced to present this case on account of the paper which Dr. Welch, of Baltimore, read at the recent meeting of the Association of American Physicians, at Washington. In that paper, which was entitled "Venous Thrombosis as a Complication of Cardiac Disease," Dr. Welch reported three cases of this unusual complication, and stated that the literature on the subject was rather meagre. In one of Dr. Welch's cases the thrombosis complicated mitral stenosis, in another mitral insufficiency, and in the third aortic and mitral insufficiency. In all of the cases the venous obstruction was on the left side. In the discussion following Dr. Welch's paper, several of the gentlemen present reported similar cases, and Dr. Cary, of Buffalo, suggested that enlargement of the left auricle might produce sufficient pressure to cause a slowing of the circulation and thus allow the formation of a thrombus. Dr. Smith said that in the case he had shown he suspected the presence of an endophlebitis.

Dr. Peabody said he thought the case shown by Dr. Smith was a good illustration of the condition which Dr. Welch had described in his recent paper. The swelling of the arm in Dr. Smith's case was an example of the so-called hard œdema, and was probably the result of a partial thrombosis or a phlebitis without thrombosis.

In reply to a question, Dr. Peabody said he thought it possible that there might be a condition of partial occlusion of a vein by a thrombus. A phlebitis might cause a swelling of the vessel, with partial occlusion, and the same result might follow upon a thrombosis.

Dr. Charles S. Bull said that not infrequently a partial thrombosis of the retinal veins was found.

Dr. Janeway said that while a peripheral thrombosis might be partial, a thrombosis of the large veins was usually complete, although it might be partial.

Dr. Andrew H. Smith said that anything which interfered with the perfect smoothness or polish of the intima might cause a collection of fibrin, and in the vein thus produce a partial or complete thrombosis.

Dr. Robert F. Weir said that in those veins in which the blood current was slow, like the varicose veins, there was a possibility of a partial thrombosis which very frequently developed into complete obstruction. It was rare to find such obstructions in the large veins, as they were usually washed away by the force of the circulation. In former days, when the Esmarch bandage was resorted to in the treatment of aneurism, it was not uncommon to see a thrombosis which filled the sac become dissipated twenty-four or forty-eight hours after the blood current was re-established, and it very seldom gave rise to any trouble in the peripheral vessels.

Dr. Joseph D. Bryant said that whenever a vessel like the external jugular was ligated with sufficient force to cause a thrombosis, the latter was very apt to become complete.

Dr. Robert Abbe said that in the jugular vein he had observed a thrombosis, apparently of the septic type, involving only one-half of the vessel wall, the rest of it being healthy. He said he had seen a number of cases of unilateral œdema of the leg, usually the right leg, in patients who gave a vague history of appendicitis. In these cases, the œdema was probably due to pressure rather than to inflammation of the vein; there was no reason to suspect septic venous obstruction. In the case shown by Dr. Smith, the œdema also seemed to indicate a venous obstruction resulting from pressure rather than from a septic process, as the latter type would be apt to give rise to more severe symptoms. Dr. Abbe expressed the opinion that, in the majority of cases, when a vein was once sealed it was permanently sealed.

Dr. Weir said that the effect of pressure on the vein as a factor in the production of œdema reminded him of the cases of extensive œdema of the arm after breast operation. In former years, when the axilla was only imperfectly cleaned out after removal of the breast, the subsequent œdema of the arm was attributed, and in many cases justly, to the pressure of the enlarged glands upon the veins, but to-day, after the most radical operation, which included the removal of all the glands in the axillary region, this œdema of the arm was even more apt to occur and to be more or less permanent. Dr. Weir said he was inclined to attribute it to the pressure of the cicatricial tissue upon the veins, thus interfering with the return circulation. Another possible explanation was that this very thorough removal of the glands interfered with the return of the lymphatic circulation.

A Consideration of Endocardial Murmurs of Organic Origin, Localized in the Pulmonary Area of the Heart: Illustrated by Two Cases.—Dr. J. W. Brannan read this paper (see page 48).

Dr. Walter B. James reported the case of a boy who had two attacks of rheumatism, both mild in character. During his second attack he developed a systolic murmur in the second left interspace, very similar to the one in the case presented by Dr. Brannan, but somewhat more distinct over the great vessels of the neck. There was no cyanosis or other cardiac symptom, and no enlargement of the left or right heart. Dr. James said he was disposed to regard the case as one of mitral regurgitation.

Dr. George L. Peabody said he thought the colored boy who had been presented by Dr. Brannan at the previous meeting of the society, and again at this meeting, had a mitral systolic murmur. It was heard very distinctly over the usual site of such murmurs. In addition to this, there was possibly some adventitious thickening in the pericardium over the apex, which interfered somewhat with the sound reaching the ear.

That would not, however, explain the intensity of the sound farther up.

Dr. E. G. Janeway said he could recall a number of cases of loud systolic murmur over the pulmonary area of the heart in which the murmur was apparently independent of a mitral lesion, and was produced by pressure on the pulmonary artery. It was possible, for example, that such a murmur might be due to pressure symptoms produced during the movements of respiration, and in such a case no explanation of the murmur could be found at autopsy. Another possible explanation of such murmurs could be found in anatomical abnormalities which could not be made out during life.

Dr. Beverley Robinson said he thought the simplest and most rational explanation of a murmur like the one heard in Dr. Brannan's case was that it was the result of pressure on the pulmonary artery, due to thickening and adhesions of the left pleura.

A Case of Pneumonia Ending Fatally with a Convulsion of Uræmic (?) Origin.—This case was reported by Dr. Beverley Robinson. This patient was seen by him in consultation with Dr. J. E. Traub, who furnished the following history of the case: Man, fifty-one years old, single; a native of Ireland, and a dry-goods merchant by occupation. He used alcohol to a considerable extent. Fifteen years ago, when he first came under Dr. Traub's observation, he complained of neuralgic pains, chiefly occipital, with headache, dizziness, dimness of vision, and insomnia. The urine at that time showed the characteristic signs of chronic diffuse nephritis: its specific gravity ranged from 1.010 to 1.015, with varying amounts of albumin and some granular casts. In 1885 the diagnosis of Bright's disease was confirmed by Dr. F. Delafield. The urine gradually cleared up, and during the past eight or nine years it was normal. On February 9, 1900, the patient had an attack of grippe, complicated by gastritis and pleurisy, with marked prostration. On February 15th he was seen by Dr. Delafield in consultation, and a favorable prognosis was given. At this time the specific gravity of the urine was 1.020, and it contained no albumin, sugar, or casts; it was acid and but slightly diminished in quantity; there was some diminution in the quantity of urates. On February 18th a pneumonia developed on the left side posteriorly. The urine was repeatedly examined with negative results. On February 23d the patient had two attacks of syncope, from which he rallied. Later in the day he had a general uræmic (?) convulsion, and died in less than a minute and a half. At the time death occurred he was perfectly conscious, and his mind was clear. Dr. Robinson said that his main reason for reporting the above case was to emphasize the importance of ascertaining the amount of the daily excretions of urea in cases of suspected nephritis, independent of the specific gravity, and the presence or absence of albumin or casts. Bearing upon this joint, he read the following letter from Dr. Frederic E. Sondern:

"In connection with cases of chronic diffuse nephritis, I take the liberty of making the following comments: After a chronic diffuse nephritis has become well established the evidences found in the urine are in the large majority of cases always characteristic, even at times when the lesion is most quiescent—polyuria, lowered specific gravity, decreased daily excretion of urea, usually small amounts of albumin and a small number of hyaline and occasionally granular casts. During the most quiescent periods the albumin, the casts, or both may entirely disappear, and at such times the only characteristic feature is the diminution in the daily excretion of urea. In my opinion this latter point is the most important and is the one which is not given sufficient attention by most observers. I will go further and say, that during these entirely quiescent periods, which may extend over a considerable time, even the polyuria may decrease to such an extent that the normal daily excretion is approached, and then these specimens very closely resemble normal ones, excepting the fact that the daily amount of urea is considerably below the normal minimum. As the normal daily excretion of urea is no constant factor, and varies between extremely wide limits, and the fact that so many other circumstances in the body metabolism affect this daily excretion of urea, it can easily be understood how some of these cases may be overlooked, and others declared cured when such is by no means the case. In following these cases, it is, I believe, extremely important to keep track of this daily excretion of urea, for it is a far better guide to the functional impairment of the kidney than is the amount of albumin or the number of casts, of which accurate record is usually kept. Of all the cases of this kind that I have followed, while the polyuria usually persists throughout, it sometimes disappears for longer or shorter periods; albumin and casts may, one or both, occasionally disappear entirely for a time, but a very critical examination usually reveals very faint traces of the former, and a thorough microscopic examination of sediments obtained by centrifuge usually shows a few hyaline casts at least. As these cases go from bad to worse, the only change sometimes observed is the continually diminishing daily excretion of urea. As the result of comparatively slight causes, acute exacerbations of this chronic condition may break out at any time, and then usually we have a picture of acute nephritis. On the other hand, a sudden uræmia may develop, quickly followed by death, without changes in the condition of the urine excepting what might be accounted for by the ante-mortem stasis. If these patients withstand the uræmic attack, subsequent specimens of urine present the picture of a renal congestion or of an acute exacerbation of the chronic lesion."

Dr. Peabody said he could not agree with Dr. Robinson as to the value of a knowledge of the amount of urea excreted in the prognosis of kidney disease. If any one fact had been established with regard to uræmia, it was that urea had usually nothing to do with it. Urea could be injected into the veins of animals in very large doses without producing any effect excepting to increase the amount of urine. Urea was given therapeutically in considerable doses. What did produce the convulsive seizure in uræmia was still uncertain. The most recent theory was in favor of the extractives, such as creatin and creatinin. The urea in the urine simply indicated the amount of nitrogenous material excreted, and must be considered in comparison with the amount taken in.

Dr. Charles L. Dana said it was not at all certain that the convulsion in the case reported by Dr. Robinson was uræmic, as no post-mortem examination was made. It might possibly have been due to an embolism or a cerebral hemorrhage or sudden heart failure. The speaker said that in his experience a sudden general eclampsic seizure in adults was very rarely due to uræmia. Uræmic convulsions, while they were sometimes general, were usually preceded by twitching and prodromata that gave us an indication of what was going to happen.

Dr. Brannan said it was generally taught that a good deal of importance should be attached to the specific gravity of the urine, and that urea was probably the chief factor in influencing the specific gravity. In advanced chronic nephritis we found, as a rule, a low specific gravity, and this generally went with a grave condition of the patient. On the other hand, if the specific gravity was high, there was usually less danger to the patient, as it indicated that the excre-

tory functions of the kidney were being performed. Of course the quantity of food taken, the presence or absence of fever, etc., must all be taken into account in the individual case.

Dr. Peabody said that while we were prone to attach considerable importance to the specific gravity of the urine, a low specific gravity did not necessarily indicate a grave condition if the patient was passing a large quantity of urine.

Dr. Andrew H. Smith said that in Dr. Robinson's case the possible influence of the pneumonic intoxication should not be overlooked Such convulsions were not infrequently observed in the course of a pneumonia in children.

Dr. E. G. Janeway said he agreed with Dr. Dana that the convulsion in Dr. Robinson's case might have been due to another cause than uræmia. There might have been a hemorrhage in the medulla or brain. In a case which recently came under his observation the patient had a convulsion which was regarded as uræmic, as it was known that the urine had long contained albumin and casts. Upon his recovering consciousness, however, one side of the patient was found to be paralyzed, showing that the convulsion was due to a hemorrhage of the brain. As regards the urine in kidney disease, the quantity and specific gravity were the important points, according to the recent experiments made by Dr. C. A. Herter. The excretion of urea was not so important. Dr. Janeway said he did not think Dr. Robinson's patient would have died so quickly from a uræmic convulsion.

Dr. Robinson, in closing, said he was well aware that the question as to the causative factor of uræmia was still unsettled. While it might not be caused by urea, still an estimation of the daily quantity of urea excreted gave us an idea of the amount of urinary solids eliminated, which was a very important factor in the prognosis of chronic nephritis.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, May 21, 1900.

Frederick Holme Wiggin, M.D., President.

Two Cases of Sarcoma Cutis.—Dr. William S. Gottheil presented these cases. The first was that of a man on whom purplish nodules appeared on various parts of the skin about six years ago. At present the condition was typical of that variety known as the multiple pigment sarcomata of Kaposi. The man had been treated for a long time with arsenic injections, and under this a number of the nodules had disappeared completely. The second case also occurred in a man who, for fifteen years or more, had had a nævus of some kind. This had given him no trouble for many years. At present, there were sarcomatous nodules at the site of the excision of the first growth. The prognosis in such a case was much better than in sarcomata of the internal organs—indeed, a few cases of cure had been reported.

Symposium on Organo-Therapy.—The evening was devoted to this discussion.

The Therapeutics of the Suprarenal Capsule.—Dr. William H. Bates opened the discussion with a paper on the suprarenal extract. He first exhibited an aqueous solution of the suprarenal gland made by him in 1894, and sterilized. With the exception of having become darker it had remained practically unchanged, and had retained its therapeutic properties. From long experience with this extract he was convinced that sterile preparations of it were harmless, their chief action being as a muscle tonic. The suprarenal extract was unique in that while one-tenth of a grain had produced the maximum physiological effect, two ounces had produced no further action. Experiment had shown that when an excess was used, the additional quantity was stored in the system.

Preparation: One part of the dried extract should be boiled in ten parts of a saturated solution of boric acid, filtered, and again boiled in the permanent receptacle. No matter how carefully prepared, the solution should not be sprayed into the nose and left there in any quantity, because under such circumstances, though sterile at the time of its introduction, it soon became putrid, and would then sometimes give rise to severe sepsis.

Therapeutic uses: In some cases of acute conjunctivitis he had been able to effect a cure by one treatment with the suprarenal extract. Excellent results followed this treatment in gonorrhœal ophthalmia. Some cases of deafness which had not been benefited by the usual treatment had resulted in a cure by the use of this extract. Operations on the nose and throat could be performed almost bloodlessly with its aid. Chronic rhinitis was temporarily benefited by its use. Dr. H. Holbrook Curtis had found it very useful in laryngeal phthisis, relieving the painful deglutition more effectively than even cocaine. The suprarenal extract Dr. Bates looked upon as a specific for hay fever. Three cases of œdema of the glottis had been reported in which the use of suprarenal extract had acted admirably. It had been found decidedly beneficial in apparently opposite states of the heart.

The Therapeutics of the Pituitary Body.—Dr. William M. Leszynsky read this paper (see page 1122, vol. lvii.).

The Therapeutics of the Thyroid Gland.—Dr. Herman M. Biggs discussed this subject. He said the whole question of thyroid therapy was still in an unsettled condition. In cretinism the influence of this treatment was most remarkable, but the remedy must be employed throughout the remainder of the person's life. The conditions in which this remedy had been chiefly used were classified as follows: (1) Exophthalmic goitre; (2) psoriasis, eczema, alopecia, lupus, and certain other diseases of the skin; (3) goitre; (4) various forms of insanity; (5) obesity; (6) retarded development in children; (7) tetany; (8) in a number of conditions, such as chlorosis, anæmia, syphilis, and arteriosclerosis, in which the remedy had been used empirically. In two instances he had used thyroid preparations in Graves' disease, and in both instances it had resulted in an aggravation of the symptoms. There seemed to be no means at present by which one could determine in what class of cases of chronic eczema or of psoriasis the thyroid preparations would be of service, for in some the results were good, while in others they were absolutely *nil*. In lupus the results following thyroid treatment were not unlike those observed after the use of tuberculin. The lupus nodules had never been completely removed by it. In leprosy there seemed to be no rational ground for the use of this remedy, yet certainly results had been secured which might at least be characterized as encouraging. Fairly favorable results had been secured in some cases of stuporous insanity, and in mental derangements occurring about the time of the menopause. In the treatment of goitre there was usually improvement, the goitre being reduced in size. In fibroid goitres there was naturally but little benefit observed. In some cases of obesity a very rapid loss of weight had followed the administration of thyroid preparations, and without any harmful effects. In these cases the dosage should be at first small, being gradually increased, while the case was kept under constant observation in order to note the first symptoms of thyroidism. A few striking results had been reported from

the use of thyroid preparations in children in whom development had been retarded without any evidence of cretinism. The chemistry of the thyroid gland was still obscure. Thyroidin had been long ago isolated. It was the proteid portion of the gland. The activity of the preparation depended largely upon the careful selection of glands from young animals, and the use of them in the fresh state for making the thyroid extract employed for therapeutic purposes.

The Therapeutics of the Thymus Gland.—Dr. S. Solis-Cohen, of Philadelphia, spoke on this topic. He said that it had long been known that in cases of so-called thymic asthma children died through some mysterious influence exerted by the thymus gland, and while many authors had written learnedly on the subject, he personally felt that they had shed very little light on it. One reason for contradictory statements from different competent observers was to be found in the varying qualities of different preparations. He had addressed a letter of inquiry to the principal manufacturers of these products, and from their replies he had learned that no two of the American products were alike. Mr. David Owen's supposed cure of a case of exophthalmic goitre by the administration of thyroid extract turned out, on further investigation, to be a case in which, without his knowledge, the butcher had substituted thymus gland. This had naturally led to the deliberate use of thymus gland from the calf. In one of his cases that showed no improvement, it was discovered that the thymus gland from the sheep had been used instead. In a case of severe exophthalmic goitre, reported by Mr. Todd, of England, recovery ensued after the use of the thymus gland from the calf, although previously it had proved most obstinate under all the approved methods of medication. Dr. Cohen said that he had personally seen many good results from the use of this gland, but he had recently abandoned it in favor of suprarenal gland extract, which acted still better. Some cases presented symptoms which were best controlled by the suprarenal extract; others yielded better to the thymus extract. On the whole, a combination of the two had seemed to work better than either one alone. Physiologists had not given us much light on this matter. We were told that the active principle of the thymus gland when injected into the veins caused extensive vascular clotting, and hence this remedy had been used as a styptic, and had been recommended in cases of hæmophilia. This extract had also been used and recommended in leukæmia, rickets, and rheumatoid arthritis. Kinnicutt and others had claimed good results from it in pulmonary tuberculosis. Chittenden had shown that the thymus gland contained an exceedingly large proportion of phosphorus, which might possibly explain some of the good results claimed for it.

The Therapeutics of the Mammary and Parotid Glands.—Dr. John B. Shober, of Philadelphia, read this paper. He said that he made use of tablets, each of which represented twenty grains of the fresh mammary gland of the sheep. The dose was from three to six tablets daily. It acted very much like ergot, though more efficiently. The bleeding from uterine fibroids could often be most satisfactorily controlled by this remedy. The tumors themselves were inhibited in their growth, and diminished in size up to a certain point. It was possible that the continued use of this remedy might indefinitely postpone operation in many such cases. He had used the mammary-gland extract in many cases of subinvolution of the uterus, and with marked success. In regard to the parotid gland, he said that this gland was taken from the sheep and prepared in the same way as the extract of the mammary gland. Its principal action was as a powerful sedative to ovarian pain, and he had employed it with entire satisfaction in those cases of ovarian neuralgia unaccompanied by marked pelvic disease. In these cases vaginal examination would show great sensitiveness, with tender and prolapsed ovaries, the latter becoming swollen just before the menstrual period. In such cases he had had very astonishing results, having cured within a few weeks patients who had suffered for many years. The treatment should be begun some time before the expected menstrual period. When there was also inflammatory disease of the tubes and ovaries he did not think anything was to be gained by temporizing with the parotid medication, as they were really operative cases; nevertheless this remedy had a very pronounced influence in relieving the pain. He recommended the parotid gland only in cases of uncomplicated ovaritis, and he found such cases rather infrequent, as he made it a rule to examine carefully the patients under ether in order to be sure of the true condition present.

Prof. Oliver T. Osborne, of Yale, opened the general discussion with a few remarks on the physiology of the subject. He said that extirpation of the thyroid, pancreas, suprarenals, and the pituitary body caused death. He believed exophthalmic goitre was the result of hypersecretion of the thyroid, as the symptoms of the two were almost identical. In his opinion, the size of the gland had been given too much prominence in discussions on this subject. There seemed to be no reason why there might not be all stages of secretion, even though the gland was not enlarged sufficiently to be easily palpated. After the age of forty years the gland began to atrophy—in other words, just at the time that persons normally put on flesh. Women constituted eighty per cent. of all cases of Graves' thyroid disease, and the same was true of myxœdema. The thyroid hypersecreted during each menstruation and each pregnancy, and these two facts taken together should afford food for thought and speculation. Those who became obese while young, from hereditary or other causes not easily ascertainable, were not usually benefited so much by thyroid treatment as persons between the ages of forty and fifty years. He was of the opinion that it was the custom to give altogether too large doses of thyroid, and he made this statement because of the very small quantity of thyroid secretion distributed through the system daily. It seemed to him rational to employ thyroid preparations in eczema, particularly in that form found in old age. Thymus, being very rich in nuclein, should do good whenever a nuclein seemed to be indicated. In regard to hypersecretion of the pituitary, Dr. Osborne said that two or three years ago he had suggested that giantism was due to this cause, and that acromegaly was the result of a perverted secretion of the pituitary. He believed that cases of giantism, if the patients lived long enough, would become acromegalic. The pituitary body consisted of two parts, the hypophysis and the infundibulum. The latter was capable of raising the blood pressure; the hypophysis gave results quite similar to the thyroid. He was now using pituitary body in two cases of acromegaly, and the results seemed to indicate its influence on acromegaly to be distinct and definite. The laboratory experiments at Yale showed that the blood pressure could not be raised by giving suprarenal extract hypodermically or by the mouth, although the pressure rose rapidly if the extract was injected into the veins.

Dr. Francis J. Quinlan said that he personally believed that suprarenal extract was second only to cocaine as an addition to our armamentarium. Acute and passive hyperæmias of the nose were promptly relieved by the use of this extract, and its action in acute colds was most salutary. It was entirely different

in this respect from the transient effect observed from the use of cocaine, and so far had not been known to give rise to any habit, or indeed to any deleterious effects.

Dr. Bates, in closing, said that it was to Dr. S. Solis-Cohen that the profession owed the knowledge, in the first instance, that the internal administration of suprarenal extract would cause a rise of the blood pressure. This was not observed in patients having a normal heart, but was very evident when there was disease of the heart.

Dr. Cohen said he had no doubt regarding the accuracy of the physiological experiments referred to by Dr. Osborne, any more than he had of the clinical observations referred to by Dr. Bates. A possible explanation of the failure of adrenal substance to produce a rise of blood pressure in normal animals was the fact that throughout the body there was a system of checks and balances—thyroid secretion, thymus secretion, and adrenal secretion—balancing one another, and preventing any excess of one or the other in the normal individual. However, in an abnormal individual, having a low blood pressure, there was no call upon these checks, and the result of the administration of the substance in question was a rise in the blood pressure.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNÆCOLOGY.

Stated Meeting, May 24, 1900.

J. Riddle Goffe, M.D., Chairman.

Nephrectomy.—Dr. J. Riddle Goffe presented a young woman who had been seen by him in October, 1894, for an ovarian cyst. He had removed this without difficulty. After the operation the urine had been found loaded with pus, and examination had revealed the presence of a greatly enlarged right kidney. With the assistance of Dr. Brooks H. Wells there had been no difficulty in catheterizing the left ureter, and withdrawing perfectly normal urine. He had, therefore, subjected her to a nephrectomy, removing the right kidney. He had used the usual oblique incision. After the removal of the kidney he had opened it and found it riddled with abscesses, varying in size from that of a pea to a hen's egg. He had followed the ureter down as far as possible, and put a double silk ligature upon it. With the exception of a sinus which had continued for two months she had made a very smooth recovery. The sinus had closed after the removal of a silk ligature. The pathologist had reported the kidney to be tuberculous, and that the tuberculous process extended down the whole length of the ureter that had been left attached to the kidney. He had then placed the woman on beechwood creosote and cod-liver oil for six months or more. She had completely recovered, and examination at the present time showed no evidence of disease. The patient was now a nurse on active duty. In another case of this kind he thought he would remove the entire ureter, cutting it off close to the bladder, and suturing the opening.

Nephrorrhaphy.—Dr. Goffe also presented a woman whose kidneys he had anchored last February. She had come to him with all sorts of nervous symptoms. Physical examination had revealed nothing but two floating kidneys. He had performed double nephrorrhaphy. On the right kidney he had made the incision through the capsule on the convex surface, and dissected back two flaps. Then turning them back, he had inserted three sutures. On the other kidney, for purposes of comparison he had adopted the method suggested to him recently by Dr. Robert T. Morris. He dissected off a saddle-shaped flap, and then passed the flap itself through the fibres of the muscle, and stitched it there. She had left the hospital at the end of six weeks, and since then her general health had improved decidedly.

Dr. A. Rose said that in cases in which this operation was undesirable, or consent was withheld, he had made use of plaster. Rubber adhesive plaster was applied so as to fasten the kidney. In cases in which he had used it the many dyspeptic symptoms that had been present had disappeared almost as if by magic. The rubber plaster had been very well borne, but he had found subsequently that it was desirable to protect the skin with Unna's zinc-rubber plaster before applying ordinary rubber plaster. He had had sixty or more such cases, and they had done very well. The plaster was more satisfactory than bandages on these thin persons.

Dr. R. H. Greene said that Dr. Goffe's second patient had come to him about six months after having been subjected to two operations at the City Hospital for some adhesions around the uterus. She complained of a general and vague abdominal pain, and his diagnosis at the time had been neurasthenia. Finding no pelvic disease he had referred the girl to Dr. Goffe, fully expecting that the neurasthenia would be aggravated by the proposed operation. It was evident, however, that he had been mistaken on that point. She was still quite neurasthenic, but better than at the time of the operation. He was not yet convinced, however, that this operation was a useful one.

Dr. S. Marx took much the same view as the last speaker regarding the real value of this operation. The improvement noted in this case, he said, could be easily explained by the better care and diet the patient had received while at the hospital. In these poorly nourished individuals the diminution in the amount of the fat around the kidney would naturally increase the normal mobility of this organ. He had treated such cases by overfeeding with equally good results. A recent laparotomy for another condition had afforded him the opportunity to see the condition of a kidney that had been anchored by an eminent surgeon one year previously. It was instructive to note that the "anchor" was six inches long, and the organ was displaced.

Dr. G. H. Balleray said he believed the kidney would soon become displaced again in this patient unless certain precautions were taken. These patients should be especially forbidden to wear corsets and to make sudden and violent motions. The skirts should be supported from the shoulders. It was also important to maintain a proper state of nutrition. These individuals were almost invariably very thin and poorly nourished. He had just examined this woman, and had found both kidneys in a normal position. Regarding the case of tuberculous kidney it was well that Dr. Goffe had not been content with simply draining the organ.

Dr. P. A. Harris said that the examination left little doubt about the operation having effected an anatomical cure in this case.

An Aseptic Gynæcological Emergency Instrument Case.—Dr. Augustin H. Goelet exhibited such a case. Packed in a convenient leather case were two trays of instruments and two enamelled trays. The latter enclosed the instruments and in this way could be utilized as a sterilizer. Curettes, clamps, and irrigators were provided, and there was room in the outer leather case for a fountain syringe and a rubber air-cushion.

Carbonic Acid Gas to Relieve Labor Pains.—Dr. A. Rose exhibited an apparatus for applying carbonic acid gas to the vagina or uterus with the idea of facili-

tating the dilatation of the cervix and rendering labor comparatively painless. In one case in which he had tested it the relief was as great as if chloroform had been administered. The mode of giving the gas by means of a simple and portable apparatus was demonstrated.

Cases Simulating Pregnancy.—Dr. S. Marx presented two specimens. The first case was that of a young woman in perfect health up to two months ago, when she skipped her menstrual period, and about one month later gave the classical signs of a ruptured extra-uterine pregnancy. On opening the abdomen he had found instead of an ectopic pregnancy two ovarian abscesses. The second case was that of a woman whose abdomen had presented the configuration of a woman pregnant at about the eighth month. She denied having been exposed, but stated that she had menstruated very scantily for a number of months past. Local examination was almost out of the question because of a nearly imperforate hymen, but a mass was felt that resembled the head of a small fœtus. No fœtal heart could be heard, but there was a very distinct and typical placental souffle. On opening the abdomen he had found a typical parasitic fibroid. Corresponding to the situation of the bruit were enormous vessels spread out in the shape of a fan. Through these vessels the main tumor, weighing twelve pounds, had derived its blood supply. The entire tumor was attached to the fundus of the uterus by a very small pedicle.

Dr. John O. Polak advised in every doubtful case of this kind to make a posterior section through the vagina. This would enable one to make the diagnosis, and it was surprising how well cases of ectopic pregnancy and pus cases could be treated by this route.

Hysterectomy for Procidentia; Ovariotomy for Ovarian Pain.—Dr. G. H. Balleray presented an ovarian cyst which he had removed from a woman supposed to have a fibroid until the abdominal section had revealed its true nature. It had a very large, broad pedicle. He also reported a case of procidentia which he had treated by hysterectomy. A third specimen was an ovary and tube removed because of severe menstrual and intermenstrual pain occurring in a working-woman. He had operated on this case because he had seen several in which there had been immediate improvement following this establishment of an artificial menopause.

Dr. P. A. Harris cautioned against doing ovariotomy for the relief of pain until the history had been most carefully considered, including the probability of the existence of salpingitis. It was only exceptionally that a good result could be expected.

Dr. Polak expressed the belief that there were very few cases of procidentia that demanded hysterectomy. This operation removed the keystone of the arch, so to speak, and unless the abdominal wall could be attached to the vagina there would be prolapse of the vaginal wall, and the woman would complain of an unpleasant sensation of pelvic weight and pain. Plastic procedures seemed to him far better.

Dr. Goffe thought the question of performing hysterectomy for procidentia depended largely upon the age and condition of the patient. In a woman nearing the menopause, who had borne her modicum of children, he favored hysterectomy, and found it simple and efficient. Ovariotomy for ovarian neuralgia was, in his opinion, rarely indicated, though it might be proper in exceptional cases that had been under careful observation for a long time.

Dr. Balleray replied that in a young woman the plastic operations should certainly be tried, but in a woman of the age of his patient he considered hysterectomy the better method.

New Instruments.

MODIFICATIONS OF BOTTINI'S INSTRUMENT FOR THE TREATMENT OF HYPERTROPHY OF THE PROSTATE BY GALVANO-CAUTERY.

By ROBERT NEWMAN, M.D.,
NEW YORK.

This instrument, suggested in former papers, is a modification of the Bottini instrument altered by Freudenberg. The reasons for the alterations have been stated in the author's paper read at the last meeting of the American Electro-Therapeutic Association, held in Washington.

Fig. 1 shows the instrument in perspective, with platinum burner shown in dotted lines slightly exposed. Fig. 2 is the end of the instrument with the platinum knife fully exposed. The instrument consists of a hollow metal shaft *B*, terminating in Thompson's curve with tunnelled end *C*. The platinum knife *D* is propelled backward and forward by means of a rack and pinion *E*. Two insulated copper wires pass through the shaft and carry the electric current to the platinum burner. The conducting cords of the battery or Edison's street current are adjusted to the instrument at staples *G* and *H*. The current may instantly be thrown on or off by means of the switch *F*. A scale and indicator *J* shows at a glance the extent to which the knife is exposed. Freudenberg's improvements on the original Bottini are very good, and were needed. On this improved instrument, the writer has made the following modifications, as shown in the cut:

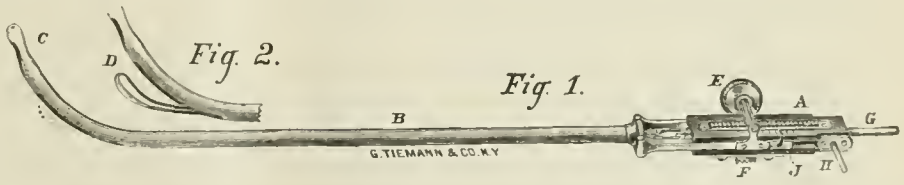

Fig. 2. Fig. 1.

(1) Omitting the water-cooler, in order to make the mechanism of the instrument simpler. The water-cooler is an impediment, takes up space, and needs for its proper management a special assistant. As the burner is smaller than in the original instrument, it does not need so much heat, and this can be controlled more easily. It has been questioned whether it is better to dilate the bladder with water or air. Each method has its own advantages and objections. But it is better to do away with the heat of the instrument which is accomplished by (2) the two conducting wires conveying the heat, attached one to either end of the burner and each running separately, being insulated. This arrangement will heat the burner immediately, and prevent the heating of any other part of the instrument. The shaft remains cool.

(3) The end of the instrument is conical and of a smaller size in order to pass any obstruction and enter the bladder more easily. Thus the operation can be performed in cases in which the larger-sized portion of the instrument could not be introduced.

(4) There is a tunnel at the conical end for a filiform guide, over which the instrument passes, to be used at the option of the operator.

(5) The burner of platino-iridium is thinner and stationary, and thereby cannot get out of shape and place, and besides the greater heat is avoided.

(6) The protector of the burner, when moved, acts at the same time as a meter, the operator thereby knowing the exact place of the burner. This burner or knife can cut to any depth, as the operator desires, and by rotating can cut in different directions. The instrument can be taken apart for cleaning and sterilization.

(7) This instrument is cheaper and costs about one-half as much as the Bottini original or the one modified by Freudenberg.

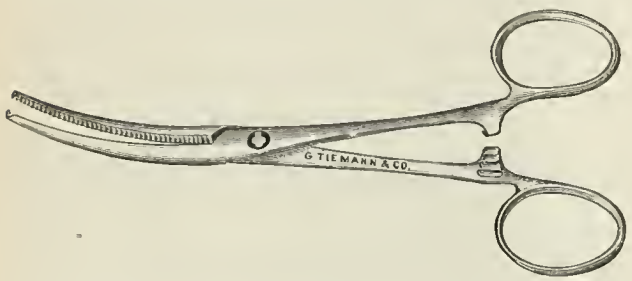
148 West Sixty-third Street, April, 1900

A MODIFIED ARTERY CLAMP.

By RUSSELL BELLAMY, M.D.,

NEW YORK.

About two years ago I had the pleasure of presenting to the Society of the Alumni of Bellevue Hospital a clamp designed and used extensively by Professor Theodor Kocher. After a long sojourn in Professor Kocher's clinic in Berne, I many times realized the great advantages of this forceps, and purchased a number from the original instrument-maker. These



clamps have proven very satisfactory, but the absence of the French lock has made it very difficult to cleanse them thoroughly, and the extreme straightness of the long blades has at times proven awkward. To overcome these disadvantages Messrs. George Tiemann & Co. have constructed for me a new clamp which has the French or detachable lock and a graceful, easy curve of the blades (see cut, two-thirds original size). The curve in the new clamp adapts itself well to angles and allows the passage of ligatures with the greatest ease.

Through the kindness of my confrère, Dr. Fielding Lewis Taylor, I have used the new clamp with the greatest satisfaction, in the clinic at the House of Relief, Hudson Street, this city.

The Detection of "Bacillus Typhosus" in Water and Other Substances.—Hankin, employing a modification of the well-known method of Parietti, claims that he has repeatedly been able to demonstrate the presence of bacillus typhosus in the water of piped supplies in Agra in which sand filtration had been employed, and also in some earth six inches from the surface of the foreshore of a village on the banks of the Jumna. Until, however, some additional confirmation is obtained Hankin's interpretation of his results must be accepted with some reserve. The facility with which the organism appears to have been isolated is strangely at variance with the experience of most able bacteriologists, who, using practically similar methods for many years, have experienced the greatest possible difficulty in attempting the identification of this bacillus in contaminated water supplies.—*Centralblatt für Bacteriologie*, 1899, Bd. 26, Nos. 18 and 19.

Medical Items.

A New Army Stretcher. — Dr. Chavernac, of Aix (France), has just designed a new army stretcher. It is a rigid contrivance made in two halves, and its advantage over the existing French ambulance is that the wounded man can be lifted off the ground without experiencing any shock or pain. The halves of the stretcher are placed on each side of the sufferer and by pressure they hold together under the body of the patient, who is not touched with hands at all in the operation. When loaded, the stretcher is mounted on a light bicycle carriage. Under the existing conditions of ambulance work in France, four men are required to lift the wounded man, but by the aid of the new stretcher only two attendants are needed.—*Scientific American.*

Treatment of Pulmonary Tuberculosis with Subcutaneous Injections of Ol. Camphor (German Pharmacopœia).—Dr. B. Alexander (*Münchener medicinische Wochenschrift*, February 27, 1900, p. 29) advocates this treatment, from which he has obtained the most satisfactory results. He refers to equally satisfactory reports of similar treatment by Professor Huchard and Dr. Faure Müller, and gives particulars of two recent cases of his own. His method consists in subcutaneous injection of 0.01 to 0.02 (1 to 2 cgm.) daily of the officinal oil of camphor, German Pharmacopœia, for febrile cases, continued for several weeks or months. For non-febrile cases he uses a much larger amount (1 dcgm.) injected daily for four days and repeated at intervals of not less than eight days. As camphor has a cumulative effect, the smaller doses will generally produce satisfactory results.—*Treatment*, April.

The Ideal Ration for an Army in the Tropics.—In the *Journal of the Military Service Institution* for May appears the thesis on "The Ideal Ration for the Army in the Tropics" which won for its writer, Captain E. L. Munson, assistant surgeon U.S.A., the prize offered in 1899 by Dr. Louis A. Seaman. Dr. Munson in the course of his essay says: "Prolonged heat exerts an unfavorable influence upon the digestive and assimilative functions. Hence work should not be imposed upon the alimentary tract in excess of its powers, and the diet should be restricted as compared with that of temperate climates, particularly since both diarrhœa and dysentery are known to be favored by the presence of a large amount of undigested food in the intestines, while tropical anæmia may be hastened by malassimilation resulting from overtaxation of the digestive powers. The respiration is much less energetic after arrival in the tropics, and this combined with rarefaction of the atmosphere and other factors results in a much less amount of oxygen being introduced into the blood than is the case in temperate climates. If the reduced quantity of oxygen available finds in the organism an excess of alimentary substances, it is evident that oxidation of the latter will be delayed if even ultimately complete, and metabolic equilibrium is thus disturbed. Further, according to Foster, the amount of heat evolved by the internal organs depends largely upon their stimulation. In the case of the salivary gland the temperature of the saliva during irritation of the chorda has been found to be 1° to 1.5° higher than that of the blood in the carotid artery at the same time; and the same author states that in all probability the investigation of other secreting glandular organs would yield similar results. Particularly is this true of the liver, an organ in which a large amount of heat is produced, as is shown by the fact that a temperature of 40.73° C. has been observed in the hepatic vein, while that

of the right heart was 37.70° C. Hence the excitation of the liver, either through the improper selection of foods or an excess of nutritive material requiring disposal, is to be avoided in hot climates. It is obvious that the consumption of any considerable amount of food for the production of internal heat is here as unnecessary as it is undesirable, while the nutritive needs of the organism require a smaller amount of material to repair the systemic losses resulting from the decreased oxidation and normally less active life of the tropics."—*American Review of Reviews.*

"Maine" Hospital Ship.—The American male nurses who served on the hospital ship *Maine* are very much dissatisfied with the manner in which they were treated on their voyage in her to South Africa and back. Of those originally engaged, but four have returned with the *Maine* to the Cape, and several of them have come home. Before starting for New York, in an interview with a representative of *Lloyd's Journal*, they gave an account of their grievances. Of the original committee and the London committee those complaining had only good things to say; all the trouble occurred on the vessel. The male nurses and the orderlies, all trained men possessing certificates of competency, and no one of whom has had less than three years' training in a public hospital, were engaged in New York. The majority of them threw up good positions on purpose to go with the *Maine*. They received agreements engaging them for a minimum service of five months, at $30 a month each. The agreements which were signed by Lady Randolph Churchill and Mrs. Blow stipulated that the male nurses should be under the control of the sister superintendent on board, and that they were to perform the nursing-duties for which their training fitted them. They distinctly understood themselves to be engaged for nursing-duties only, and that the rough work of the wards would be performed by hands engaged for the purpose. When the *Maine* had got to sea on her way to the Cape they were ordered to clean the vessel's wards. Before they arrived at the Cape the water had become almost undrinkable owing to the rusty tanks in which it was carried. Much of the food was so bad that it could not be eaten. On reaching the Cape the nurses learned to their astonishment that the *Maine*, instead of becoming a hospital ship on the coast as they were told she would be, was to return to England with a number of convalescents. At whose instance this alteration in the original plans was made they could not say, but all agree that the vessel was entirely unfitted for the conveyance of the sick, though suitable enough for receiving and nursing the worst cases. On the voyage back to England the nurses were treated exactly as they were going out, with the addition that they could obtain nothing to drink on board except ginger ale, which was supplied them at twelve cents per bottle. Their sleeping-accommodation was cramped. In addition to the male nurses there were four female nurses on board, but they were found to be entirely out of place; complaints of their being in the way and interfering with work were continual, and thus it is the vessel returned to Cape Town with male nurses only.

The Boer and his Medical Advisers.—The Boer is not given to "nerves" as a rule, but when his health fails him he loses heart at once. About half the population of the Transvaal suffer from indigestion. This of course is the natural outcome of an unvarying diet of boiled mutton, and bread of the consistency of putty. When a member of a Boer homestead is taken ill the family first of all draw on their old homely remedies, but if these fail they have recourse to the store. The storekeeper is the medical adviser for the district. Every trading-store keeps on hand a large supply of patent medicines. When the patient, if he is able to travel, comes over and describes his symptoms the storekeeper will prescribe for him. The Boers as a rule have not much ready cash, but what little they do possess they cling to, and the first question the patient will ask is, how much does it cost. The storekeeper of course does not recommend the cheapest article in his stock, and the Boer will say: "But that is too much, I am very ill; I may have to take many of those bottles. No; I will buy something cheaper." And he will go over the medicine shelves and will get the trader to tell him what each one is and what the writing on it says. Time is not of much importance in the Transvaal, as trade is never very brisk at the up-country stores; in fact, it is a very rare occurrence to find two customers in a store at the same time. So the trader will light his pipe and go over the stock with his customer. After a time the latter will decide on what he will purchase, and will carry off a supply sufficient to last an ordinary man for a lifetime. Should this not do him any good he will return later on and endeavor to get the storekeeper to exchange the balance of what he has on hand for some other medicine. The number and variety of empty phials and boxes to be found in a Boer house are something alarming. The Boer takes a kind of gloomy pride in his illness, and when he recovers will treasure all these as mementos, and will bring them out and show them to any neighbor who may call on him. "See," he will say, "I took all this medicine when I was ill, and this is the only one that did me good. It is good medicine this. I am always going to take it when I am ill again." And his visitor will sympathize with him and will probably take away an empty bottle so that he may know what to ask for when he gets ill himself. Besides the storekeepers there are others who supply the Boers with cures for all the "ills that flesh is heir to." These are the peddlers who travel from farm to farm selling patent medicines and trinkets. As a rule they give away a trinket with every bottle purchased, and many of them make a good living at the business. The Boer believes anything that is told him where medicine is concerned, and these people take advantage of the fact. It is not so long ago that smallpox broke out in the Transvaal. At that time an ingenious individual amassed a respectable pile by travelling through the country vaccinating people with condensed milk. Besides all these the Boer has a medical adviser in his Hottentot servant. The Boer regards every "nigger" as an animal, but he knows that the Hottentots are really very clever at curing simple ailments with herbs, and he often falls back with satisfactory results on the "Tottle" woman when all else has failed him.—*Indian Lancet.*

Balneotherapy as Practised by the Indians.—Dr. Richard K. Macalester, of Glenwood Springs, Colo., writes that the healing properties of the Glenwood Springs thermal waters were, many years prior to the advent of the first settlers, appreciated by the Ute Indians who populated this district. They called the largest spring, with a flow of seventeen hundred gallons per minute, Yampeh (Little Bear), and utilized its waters for bathing and drinking purposes. Besides this there are numerous other springs of uniform chemical constituency of their sulpho-saline-alkaline waters, and a temperature of 126° F., in which the average person can hold his hand but a few seconds without experiencing great discomfort. The Utes are said to have come from far and near in search of health at this natural sanatorium, and when a patient was pronounced to be a fit subject for balneological administration by his wise medicine-men, the following method was employed: Across two long poles a

blanket was stretched and fastened, on which the victim was laid. His comrades then, grasping the ends of the poles, raised and carried him to the hot pool, in which he was immersed. A cry of agony, or the length of endurance, was the signal for the "bath attendants" to lift him out of the water, and with brief intermissions this procedure was repeated as often as the patient could stand it.

The Indians were also not unfamiliar with the virtues of the unique cave baths, which are small caves in the rocks by the river side, in the floors of which thermal springs boil up, heating and saturating the air with vapor. These baths are very potent in an eliminating sense, exerting a specific sudorific action far in excess of plain water vapor of a much higher temperature.

Twenty Per Cent. cash is offered to physicians sending patients to a certain Thousand-Island Hotel. How pleasantly inclined toward the family physician would the paterfamilias feel some morning after a bad breakfast, if he should pick up one of these left-over tempting circulars and discovered why his doctor was so anxious for him to patronize this particular house!

Utilization of Putrid Meat in France.—*The Medical News* states that putrid meat is utilized in France, where nothing is allowed to go to waste, in a highly ingenious manner. Meat unfit for food and the bodies of animals that have died of disease are extensively used for the manufacture of superphosphates. The meat is placed in a vat containing sulphuric acid, which separates the resulting nitrogenous products from the fat. The dead animals are thrown whole into covered lead-lined vats full of sulphuric acid. If these animals have died from anthrax or glanders they are cut up before being thrown in. In the course of forty-eight hours the fat alone remains and the animalized sulphuric acid, rich in nitrogenous substances, is drawn off and sent through an underground conduit to the superphosphate factory. Thus, instead of the unsanitary method of burying such putrid substances in the ground, they are effectually disposed of, all infectious germs being completely destroyed; and there results a product available in the manufacture of a valuable fertilizer.

Medical Comforts Supplied to the South African Troops.—The term medical comforts embraces a number of articles which fall outside ordinary victualling and are intended for the use of sick men. They are all supplied from Woolwich, and their preparation forms an important department there. They are packed in "panniers" and boxes. The former are intended to be carried by mules—two panniers, weighing ninety-two pounds each, to a mule. The contents of the panniers are as follows: Brandy, one bottle; port, one bottle; whiskey, two bottles; arrowroot one and one-half pounds; sago, one pound; extract of meat, six pounds; bovril, three pounds; condensed milk, sixteen tins; sugar, six pounds; also mustard, pepper, salt, candles, matches, soap, spirits of wine, with knives and forks, canisters, spirit lamp, and other necessary hardware. Two panniers go to each field hospital, two to each bearer company. The contents of the "medical comforts box" are similar, but it holds less and is more portable. The wine and spirits are all bottled at the depot, as is the rum used for rations, and a very considerable business it is. Two pipes of port, about one hundred and twenty dozen, are bottled every day, and a corresponding quantity of whiskey and brandy, but the rum handled there runs to twelve hundred gallons a day. It is not supplied in bottles but in wicker-covered gallon jars, two jars to a case. Rum is the only alcoholic liquor served for rations. Its use appears to be traditional, but it does not strike one as particularly suited to the climate of South Africa. For the purchase of liquor the services of an expert taster are engaged. He periodically makes a selection from a series of numbered samples without knowing their origin, so that no favoritism is possible. Spirits are reduced to twelve and fifteen degrees below proof before bottling, by the addition of distilled water.—*London Times.*

Action of Soil on the Plague Bacillus.—Dr. Z. Yokote (*Centralblatt für Bacteriologie*, Abth. 1, Bd. 23, No. 24) took mice that had died of infection with plague bacilli, placed them in wooden boxes, and buried them in garden soil which was kept from thorough drying. The boxes were exhumed from time to time and the contents examined to ascertain if infective material still existed. The longest time that elapsed between the burying and the demonstration of the still virulent organism was thirty days, and the higher the temperature and the more active the rate of decomposition the shorter the life of the organism. The soil in the immediate vicinity of the boxes was examined for the organisms, but the results were negative.—*American Journal of the Medical Sciences.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended July 7, 1900:

		Cases.	Deaths.
Smallpox—United States.			
District of Columbia, Washington	June 23d to 30th	4	
Illinois, Chicago	June 23d to 30th	2	
Indiana, Evansville	June 23d to 30th	2	
Indianapolis	June 23d to 30th	1	
Michigan City	June 24th to July 1st	1	
Kansas, Wichita	June 23d to 30th	6	
Kentucky, Covington	June 23d to 30th	16	
Louisiana, New Orleans	June 23d to 30th	12	3
Maryland, Baltimore	June 23d to 30th	3	
Cumberland	June 16th to 23d	3	
Massachusetts, Fall River	June 23d to 30th	3	
Ohio, Cincinnati	June 19th to 26th	10	
Cleveland	June 23d to 30th	10	
Portsmouth	June 23d to 30th	1	
Youngstown	June 23d to 30th	2	
Pennsylvania, Pittsburg	June 23d to 30th	3	
Smallpox—Foreign.			
Austria, Prague	June 8th to 16th	8	
China, Hong Kong	May 19th to June 2d	1

THE EVIDENCES OF PROSTATIC ATROPHY AFTER CASTRATION.

BY EDWARD L. KEYES, JR., M.D.,

NEW YORK.

As in its physical structure a chain has the strength of its weakest link only, so it is in the chain of argument. The glamour of its apparent strong points cannot long hide its inherent weakness. Yet in the latter case each really strong link adds a real value to its weaker brethren and thereby merits prominence and consideration.

Such a link in the chain of pathological evidence which is gradually encircling the claims of castration as a cause of prostatic atrophy is presented in this paper in the entirety of its hard facts, namely:

(1) A large glandular prostate; (2) castration; (3) the lapse of sixteen months; (4) undiminished size of the prostate to rectal touch, undiminished length of the urethra, undiminished persistence of the clinical symptoms; (5) prostatectomy with shelling out of two solid tumors the size of pullet's eggs; (6) failure by an expert to find any evidences, macroscopic or microscopic, of atrophy of the prostate.

Nowhere in surgery are pathology and practice apparently drawing wider apart; nowhere does the microscope seem to give the lie more absolutely to clinical reports of hundreds of observers scattered over two continents than in the matter of castration for hypertrophy of the prostate. Born in the brains of White[1] and Ramm[2] independently and at about the same time; founded upon a theoretical homology between the hypertrophy of the prostate and uterine fibroma, and the results of castration on the latter class of tumors; and fortified by experiments upon animals and a few clinical data, the operation of castration for the cure of hypertrophy of the prostate was formally presented to the world in 1893.

Since then seven years have passed, and this summer the International Congress at Paris purposes to enlighten us upon the present state of the question. It is to be hoped that the discussion then entered into by many of the leading lights of the genito-urinary world will help to determine more accurately than ever before the advantages and limitations of the various methods of treatment. The Bottini *renaissance* is of too recent a date to receive an absolutely impartial verdict; but castration and the allied operations can now be rated at their true worth.

The history of castration as a method of sexual depletion may be divided into three overlapping periods. During the first period, which reached its highest expression in White's essay of 1895,[3] enthusiasm ran riot, and asexualization was hailed as the prostatic's Utopia. The second period, beginning with Albarrin's report to the French Congress of Surgery in the same year, and reaching its climax in Cabot's[4] report of the year following, and the erudite researches of Albarrin and Motz in 1898,[5] was one of adhesion to the primary principles with a beginning of wholesome doubt and careful investigation, but indefinite conclusions. The third period, one of firm convictions based on pathological findings, was first voiced, as far as I have been able to learn, by Floderius[6] in 1897, and will culminate, we trust, in the coming congress.

In the early days, in spite of the protests of a few men (Keyes and Alexander in this country), the general enthusiasm over a novel and comparatively simple surgical procedure promising such brilliant results dazzled the cautious and emboldened the incompetent, while the accumulation of favorable evidence from all sides soon overbore all but the most sceptical. Comparative anatomy, embryology, pathology, teratology, each contributed its share to round out with scientific fulness the monument of clinical success. There were flaws—here and there a failure to attain the anticipated result, in one report an undue mortality, in another the warning of post-operative dementia; but these availed nothing to check the pendulum of public opinion, and White was able to publish, in 1895, a table of one hundred and eleven cases with twenty deaths, chiefly attributable to uræmia uninfluenced by the operation or induced by the anæsthesia and shock. In the mean while various similar but less radical operations were advocated. Sir Reginald Harrison[13] introduced vasectomy, of which twenty-two cases with seven deaths (all at the hands of a single surgeon) were tabulated by Cabot in 1896.[4] Unilateral castration, angioneurectomy of the cord, and the injection into the testicle of irritating fluids for the purpose of producing atrophy were not slow to follow.

But the success of these latter operations did not bear out their early promise in any large proportion of cases, and although many surgeons continued and still continue to employ them undaunted, the ever-increasing number of failures and relapses encouraged closer scrutiny into the merits of the whole class with a less prejudiced eye and a fuller equipment of pathological facts than had hitherto been available.

This second period of searching investigation but hesitating conclusion is ably expressed in the essay of Albarrin and Motz* (1898).[5] These observers enforce by personal observation the following conclusions:

"I. Atrophy of the prostate occurs after castration in all the animals that have been tested: viz., the horse, the ox, the hog, the dog, and the cat. This atrophy is constant whatever the age of the animal employed.

"II. However incomplete the array of facts we have cited, they seem to prove that double castration in infancy prevents the development of the prostate.

"In the absence of direct evidence it is impossible to say that the same operation performed on an adult or an old man would produce similar effects; but, judging from experiments on animals, it is fair to assume that this atrophy should result" (p. 23).

So far the agreement between science and practice

* This in spite of the fact that their tables of cases, which I have been at pains to verify, are full of inaccuracies. Thus among the cases of double castration, Nos. 4, 93, and 94, are identical. The same is true of Nos. 5 and 43, 6 and 72, 7 and 8.

is complete. But from the series of nine autopsies after castration that they are able to collect from the reports of White,[3] Griffiths,[7] Kelsey,[8] Bryson,[9] Mansell Moullin,[10] Watson,[11] Socin,[12] Colley,[13] and Cabot,[14] they conclude (p. 35) that "all we can say is that no autopsy has shown a real atrophy, and that in four autopsies performed at five, seven, eight, and twelve months after operation respectively, there has been no macroscopic evidence of a diminution in the volume of the prostate. In one of these observations, Bryson's,[9] in which the castration dated back a year, the microscope showed no trace of atrophy."

Yet in the teeth of these facts the authors conclude from clinical data (p. 47), that:

"1. It is rational to admit *a priori* that double castration would diminish the volume of the hypertrophied prostate, especially in the glandular varieties.

"2. Although the anatomo-pathological data are insufficient, clinical experience proves that there is a diminution in the volume of the hypertrophied prostate after castration.

"3. The diminution in the volume of the prostate is due at first to the decongestion of that organ, and later to a real atrophy.

"4. This atrophy may come on slowly, appearing as late as six months or even later after operation and progressing for more than two years. Finally the prostate may be no longer distinguishable by rectal touch.

"5. In certain cases the atrophy may predominate in certain parts of the gland. It may involve lobes jutting into the bladder.

"6. It is impossible to say at the present day that every prostate atrophies after castration, or how much atrophy may be expected in a given case. It is even probable that in certain cases atrophy fails to occur."

These conclusions unfortunately attempt to reconcile the pathological facts with the clinical figures by minimizing the force of the former. But despite this fact the formal array of pathological findings marks an advance from which there is no retreat. The stress laid upon the immediate effect of decongestion forms the central point of later theories, and the critical discussion of the two pathological reports upon which enthusiasts chiefly based their claims is extremely fair. The pith of those reports—White's and Griffiths' —is as follows:

White[3] states briefly, of a prostate removed from a patient who died the second day after castration, that "the stroma of the gland shows beginning proliferation of the connective-tissue cells, but especially of the muscle cells. The acini tubules are also becoming filled with proliferated columnar cells, and here and there some fine granular matter may be seen in the tubules; some of the cells appear to contain fine granules which have not taken the stain, evidently fat. The changes are typical of beginning atrophy."

Griffiths' reports a similar case in which he found in a prostate removed at autopsy eighteen days after castration, (1) proliferation of the epithelium, (2) acute fatty degeneration, disintegration and absorption of the cells cast off into the lumen of the tubules, (3) a shrinking of the tubules with transformation of their usual cylindrical epithelium into cuboidal and pavement cells, and (4) proliferation of the muscular and connective-tissue elements.

Albarrin refuses to accept the proof offered by these authors as conclusive, arguing that the picture of cell proliferation and epithelial degeneration as they present it is not uncommonly the evidence of inflammation in a hypertrophied prostate, and moreover, "in the numerous experiments [of castration] that we have made, we have never seen cell proliferation result" (p. 28). And again on page 30: "We cannot admit this proliferation of the tissues constituting the stroma; it is in direct contradiction to the results obtained in all animals. Apparently there is question in this case [Griffiths'] of simple inflammatory phenomena superimposed upon the classical lesions of prostatic hypertrophy."

A critique of these opposed views would carry us beyond all bounds. Suffice it to say that Kirby's animal experiments bear out White's view; but the trend of recent investigators is all in the other direction. Since Motz's[15] able theses, the "prostatic myoma" of Thompson and others is disappearing from the nomenclature, and hypertrophy of the prostate is recognized to be a hypertrophy of all the normal elements of the gland, but especially the epithelium, an adenoma, in short, in which secondary changes of an inflammatory character—round-celled infiltration going on to sclerosis—are frequent.

Atrophy, on the other hand, begins in the epithelium, not as a result of an overgrowth in the stroma, but with the result that the stroma subsequently fills, in part at least, the space left by the atrophic epithelium. Such a change could scarcely be expected within eighteen days. Subsequent commentators, be it noted, have accepted Albarrin's conclusions either explicitly or implicitly.

We must go back a year to reach the monograph of Floderius,[6] the inauguration of the third period. This author, collecting the previous pathological findings and adding two cases of his own, concludes that there is no pathological evidence to show that castration ever did cause atrophy of the hypertrophied prostate. The evidence unfortunately was scant and is so still, but three years later the verdict is the same. No one since White and Griffiths has (to my knowledge) claimed to possess a case showing microscopical evidence of atrophy after castration.

Before tabulating the authorities I have been able to consult, I add a case which has fallen into my hands. The patient's history is as follows:

H. J——, an Irishman, carpenter by trade; sixty-three years of age; married; presented himself on August 31, 1898, suffering intense dysuria. He denied gonorrhœa or sexual excess in youth. His urinary organs and functions had been entirely normal until the autumn of 1897, when he was seized with an acute complete retention of urine. A physician relieved him by passing a catheter and taught him the use of the instrument. The complete retention lasted a week and then rapidly disappeared, so that the patient was able to dispense with the catheter until June, 1898; at that time he began to suffer some little pain on micturition. In spite of, or perhaps on account of, the use of the catheter the dysuria increased; until a few days before I saw him he had to resort to a woven catheter. This gave him little relief and brought blood every time he used it, every hour or two, day and night.

Physical Examination: The patient is anæmic, feeble, and flabby. Heart and lungs normal. No œdema except a puffiness under the eyes. The urine is drawn at eight and a quarter inches. It is ammonical and so filled with blood and muco-pus as to be unfit for any test. The bladder capacity is three ounces, practically all residual; no atony. The searcher detects no stone. By the rectum the prostate feels large and firm. It contains no nodules, nor is it tender. The vesicles, which can barely be reached, are not distended. The kidneys are not tender and cannot be felt.

By exchanging his woven catheter for a small rubber one (11 F.) his hemorrhages were checked. He was made, as far as possible, to use the catheter but three times a day and to wash daily with boric-acid solution. For six weeks irrigations of silver nitrate, sublimate, and thallin sulphate were tried, while salol, urotropin,

boracic acid, oil of wintergreen, and strychnine were administered internally in various combinations. At the end of this time the urine was but slightly less muddy; the bladder capacity had risen to four ounces. On the other hand, although he had given up his work, he was growing progressively weaker, and urinating in great distress every half-hour. Although having no great faith in the efficacy of castration, I did not think he would survive prostatectomy or endure a permanent catheter.

October 18, 1898, double castration was done through a single incision in the raphé. I neglected to search for stone while the patient was under chloroform.

The patient remained in bed for ten days, but in spite of the rest and systematic medication, general and local, he left the hospital but little improved, urinating hourly, using the catheter nearly every time. A month later he urinated every one and a half to two hours day and night. The urine was clear enough of pus to test for albumin, of which it contained one-half of one per cent. by weight. Specific gravity was 1.012. His pains were no less. I then lost sight of him till October 2, 1899; at that time he was urinating hourly, depending almost entirely upon the catheter. Although he had continued his daily boric-acid wash his pains were unrelieved. He came on account of a profuse hemorrhage of the bladder lasting several days. He brought with him a small, faceted phosphatic stone that he had recently passed. He stated that he was no stronger than at the time of operation, but he looked brighter. The prostate seemed undiminished. The urine was full of blood, the urethral length undiminished. He passed two ounces of urine voluntarily and then six ounces by the catheter. A few days later I touched a stone. He refused operation, and did not return until February, 1900, his local and general condition still unchanged.

On February 22, 1900, epicystotomy was done under chloroform anæsthesia. The bladder wall was thick and congested but fairly smooth. The prostatic obstruction was in the form of a horse-collar, the right and middle lobe constituting the major part of the tumor. Thirty-two phosphatic stones weighing five hundred and eighty grains (37.58 gm.) just filled the *bas fond* to the level of the bar. These were removed, and a median incision made with serrated scissors through the whole thickness of the bar. Through this incision two tumors were easily enucleated from the bar and right lobe, measuring respectively one and seven-eighths by one and three-fourths by one and one-fourth inches, and one and one-half by one and one-half by one and one-fourth inches, and weighing seven hundred and sixty grains (49.24 gm.). The suprapubic wound was partly sutured, with double tube drainage. The operation was performed in forty-five minutes. Convalescence was uneventful save that union was delayed by persistent sloughing of the whole surface of the wound, which could not be controlled until the urotropin (of which a daily dose of 1 gm. was being administered) was withdrawn on March 8th. A month longer was required for the slough to separate and the wound to heal.

April 12th: He urinates without pain every two hours day and night. The urinary distance is seven and three-fourths inches; residuum, one ounce; bladder capacity, six ounces. The urine is still slightly ammoniacal.

May 5th: The urethra is now only seven and one-half inches long. The residuum is down to three drachms. The urine is acid and only slightly hazy. The prostate feels rather smaller than usual; the right lobe is a little larger than the left. Although he still urinates every two to three hours day and night he has no pain whatever, considers himself entirely well, and is trying to get back to work.

The tumors removed from the prostate were forwarded to Dr. H. T. Brooks, whose report is appended:

"New York City, May 11, 1900.

"Microscopic examination of the sections made from the prostate you forwarded, February 23d, shows

Fig. 1.—Leitz 3, ocular 4

a very richly muscular and glandular structure, and a slight amount of fibrous connective tissue. The preparations were stained in hæmatoxylin alone, also in hæmatoxylin and eosin, and in borax-carmine, all parts of the tissue staining deeply and distinctly.

"The muscular structure is arranged in broad and slender bands, some straight, others tortuous, chiefly densely interlaced in a manner closely simulating the distribution of the muscle elements in the uterus.

"The glands are of the tubular variety, lined with a single, sometimes double row of short columnar or

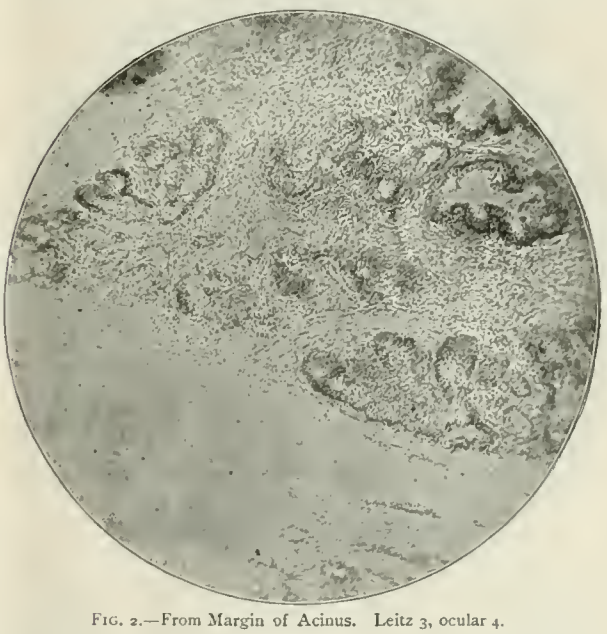

Fig. 2.—From Margin of Acinus. Leitz 3, ocular 4.

cubical epithelial cells which lie upon several layers of smaller and more rounded cells resting against the basement membrane. The great majority of the tubules are grouped closely in a more or less regular manner, presenting collectively the appearance of

lobuli in section (Fig. 1). In some areas, on the other hand, the ducts are widely separated from each other by broad bands of muscular tissue including a small number of fibrous elements (Fig. 2). In many instances the inner surface of the tubules is convoluted

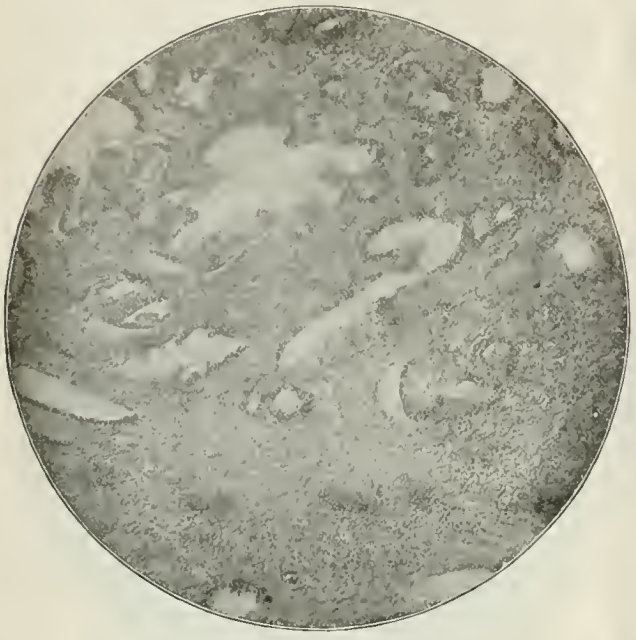

Fig. 3.—Bausch and Lomb ⅔, ocular 1 inch.

or thrown into folds in the form of papillæ (Fig. 1); in the greater number, however, these surfaces are smooth and the tube lumina round or oval in form. Most of the ducts in the groups above mentioned appear to be in every way normal, the muscle structure and epithelium being regularly arranged and perfectly formed, and the lumina free from any deposit (Fig. 3). Pigmentation of the epithelia is rarely noted and when observed is of but slight degree. Occasionally ducts are seen which are filled with a fine granular material staining faintly with eosin; others contain a small number of isolated, partially disintegrated

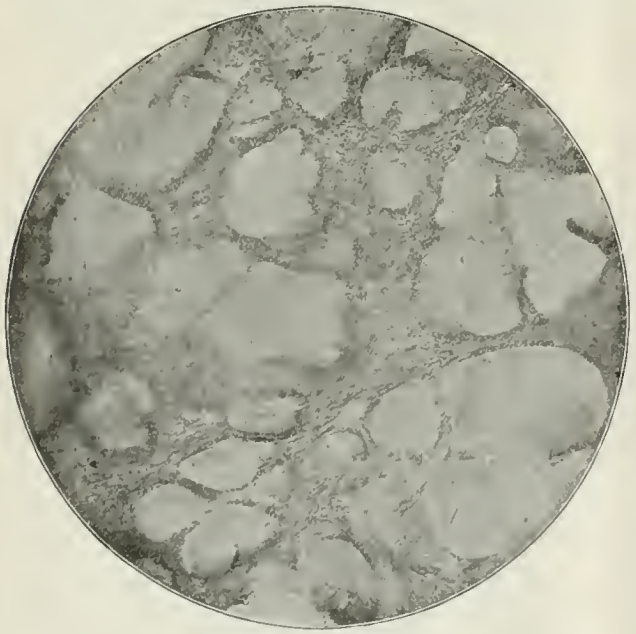

Fig. 4.—Bausch and Lomb ⅔, ocular 1 inch.

cells of epithelioid type apparently derived from the lining epithelium. At wide intervals in the tissues several lobuli are observed in which the tubules are greatly dilated, often of cystic nature, and the internal surfaces of former healthy ducts flattened and free from convolutions, the epithelia, however, retaining their normal columnar or cubical form, and only exceptionally approaching the flat squamous or endothelial type of cells (Fig. 4). Some of these dilated ducts are completely or partially occluded with a coagulated, finely granular, almost homogeneous deposit occasionally enclosing cells (Fig. 5, *A*). Corpora amylacea are rarely met with.

"There is but a small amount of fibrous tissue observed, and this appears to be chiefly confined to those areas immediately surrounding the lobuli, particularly those containing dilated ducts. It is always mixed with muscle elements—never alone. The only evidence of active proliferation in the sections—which measure 3 x 1½ cm., and extend from the external capsule to the centre of the prostatic tissue—is shown by round-celled infiltration between the muscle and connective-tissue fibres encircling the lobuli and surrounding the individual ducts of the latter. This infiltration is met with at wide intervals, being in some places diffuse, in others localized, in more or less nodular form, resembling somewhat the smallest solitary lymph nodes of the intestine or the Malpighian corpuscles of the spleen (Fig. 6).

"The insignificant amount of fibrous change, the comparative infrequency of dilated or cystic degene-

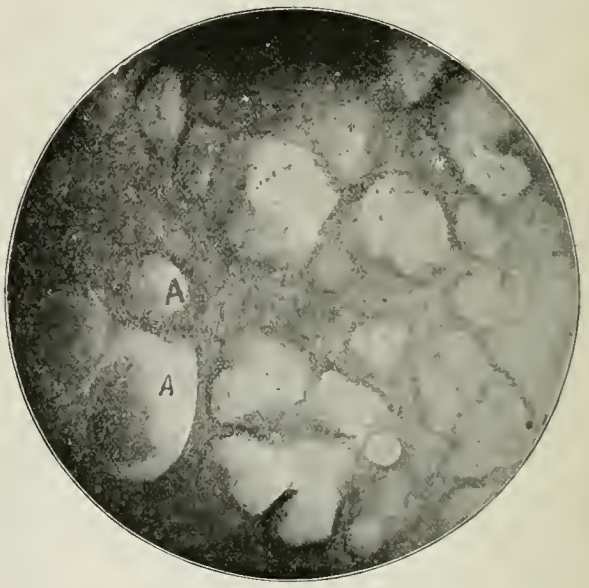

Fig. 5.—Leitz 3, ocular 4

rated tubules, and the very large amount of muscle tissue would, it appears to me, indicate that there had been but very slight development of fibrous connective tissue, *i.e.*, fibroid induration; for it is reasonable to suppose that, had this process (fibroid induration) advanced very far there would have been more decided microscopical evidence of it, and also a greater number of dilated or cystic tubules resulting from the obstructing constrictions on the efferent side of the ducts. This view seems to be supported by the exceptional occurrence of fibrous bands, which, as has already been stated, are, when present, chiefly pronounced throughout the sections in those areas immediately surrounding the gland acini.

"Another interesting feature, to me at least, is the comparative absence of corpora amylacea, which are rarely observed and then only in very minute form with ill-defined concentric lamellæ. If we accept the views of Zahn, Favre, Posner, Hildebrand, Seigert, Stilling, and others, as to the origin of these bodies, namely, that they are derived chiefly from the degenerated epithelial elements and abnormal secretions of the ducts, it would seem that there should be a very much larger number of corpora amylacea present in

this case—provided it is assumed retrogressive changes have occurred in this particular instance.

"In conclusion I may say that, judging from the collective histological appearances, it is my opinion

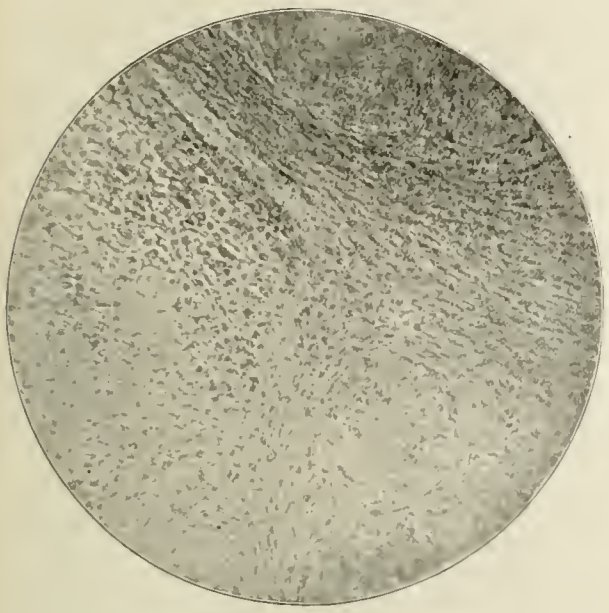

Fig. 6. Leitz 6, ocular 4.

that the changes noted in the preparations made from this prostatic tissue are no more pronounced than are those frequently observed in many so-called normal prostates. H. T. Brooks."

The table below shows briefly the status of all the similar cases I have found in the literature:

Reporter.	Time Elapsed since Castration.	Atrophy claimed.	Pathological Findings.
Kirby[3] (White) ..	2 days.	Yes.	Desquamation and fatty degeneration in the epithelial cells. Proliferation of stroma.
Floderius[6]	8 days.	No.	Gives a detailed description of which I was unable to obtain an accurate translation.
"	11 days.	No.	
Moullin[10]	9 days.	No.	"No histological changes" though the prostate had shrunken.
Cabot[4]	7 days.	No.	Sections resembled those made from the prostate of a non-castrated patient.
Griffiths[7]	18 days.	Yes.	Same findings as Kirby.
Lennander[14]	8 days.	No.	Fatty degeneration of the epithelium "doubtless inflammatory."
De Rouville[15]	35 days.	No.	Fibrous hypertrophy. "Atrophy could not have been expected."
Cabot[4]	49 days.	No.	Glandular elements sparse, muscle tissue increased (?). No considerable diminution in size of gland.
Brooks* (Kelsey).	5½ weeks.	No.	Detailed report showing no degenerative organs.
Bryson[9]	12 months.	No.	No reduction in size; no evidence of degeneration.
Brooks (Keyes) ..	16 months.	No.	No reduction in size; no evidence of degeneration.

Here then are twelve cases in which the condition of the prostrate after castration was tested by the microscope. Only two of the reporters believed they found "beginning atrophy"; and this opinion was based on grounds not acceptable to other authorities, while the time allowed for the occurrence of degeneration, two days and eighteen days respectively, is suspiciously short in view of the negative results obtained after much longer periods, viz., five and seven weeks, twelve and sixteen months.

On the whole, therefore, it is fair to conclude that in no case has atrophy been shown by microscopical examination, while in a number of cases (in the last five of the twelve cases cited, at least) it has been shown not to exist at a time when some evidence of it might have been expected.

So much for the pathology; now for the clinical facts. These may be briefly drawn from the tables of various authors, although the vagueness of statement in most of these statistics has forced me to compile some of the percentages myself, thus:

Reporter.	Number of cases.	Cured.† Per cent.	Improved. Per cent.	Unimproved. Per cent.	Died. Per cent.
White[3]	111	46.4	28.3*	7.3*	18
Albarrin[5]	126	43.7	35.7*	5.5*	15
Wossidlo[16]	154	27.3	47.4	9.2	16

* Estimated.

† Including all those "satisfactorily well," though still suffering from slight cystitis, etc.

A suggestive feature of this table is the contrast between the fluctuations of the "cured" and "improved" columns and the agreement of the mortality and "unimproved" figures. Though figures are notoriously misleading, this suggestion hints at how wide a scope is possible in reporting a case, how easy it is to feel that the prostate has "diminished," to mistake the improvement due to decubitus and systematic local treatment for a result of the operation, and above all things to report the case too soon. If the primary effect is purely a reduced congestion, and the real atrophy is not to be expected for three months or a year (Albarrin), the vast majority of the cases reported at the end of three months or six months as cured are absolutely valueless in the matter of ultimate prognosis. There is the popular phrase, "The operation was a great success, but the patient died."

Cabot's[17] recent article (1899) voices a change of sentiment which must have been felt by others than himself. In 1896 he was able to commend orchidectomy, but three years latter he reports a personal series of nine cases, of which one, probably malignant, may be thrown out. Of the eight remaining, three were unimproved; five improved, but of these three relapsed; two cures against six failures (subsequent prostatectomy cured three out of four of these; the fourth patient died).

This is the kind of statistics we need, and enough time has now elapsed since the earlier operations for

Fig 7.—Tumor of Prostate in Section.

those men who have conscientiously followed their cases to be able to produce clinical information of a quality to command as much respect as the pathological data. Until then the surgeon must regard the statistics on castration—as well as the eminently unsurgical procedure of Bottini—with interest rather than credulity.

To sum up:

1. Experiments, whether on man or the lower animals, relating to the normal prostrate do not of necessity apply to the enlarged prostate.

2. I know of no direct pathological evidence that castration has ever caused atrophy of a hypertrophied prostrate.

3. There is direct pathological evidence that in a few cases castration has failed to cause atrophy of the hypertrophied prostate.

4. The majority of cases reported thus far have been labelled "cured" or "improved" so soon after operation that many of them are doubtless instances of local depletion.

5. Clinical evidence of this is afforded by relapses occurring months after the operation.

6. Of the permanent cures some may well be instances of permanent advantage derived from reduced congestion.

7. The clinical evidence as to the actual atrophy of the prostate after castration lacks, as yet, its scientific confirmation, and has failed thus far to prove its title to the surgeon's credence.

NEGLECTED CLINICAL OPPORTUNITIES IN AMERICAN MEDICAL CENTRES.[1]

By S. A. KNOPF, M.D. (Paris and Bellevue, N. Y.),

new york.

Mr. President and Fellows of the American Academy of Medicine: For an ordinary practitioner like myself, not connected with any institution for instruction, to venture to address this distinguished academy on so important a subject as the clinical teaching of medicine may seem temerity to many of you; but, while I lay no claims to any experience as a teacher of medicine, I have spent wellnigh ten years as a regular medical student in this country and abroad, and I believe I have learned something of the needs of such a student in regard to clinical instruction. I do not intend to imitate the critics who are in the habit of depreciating American institutions to eulogize foreign medical schools. There are a good many of the latter which are far from being perfect, and certainly not any better than some of our own.

What I desire to do is to point out to you, many of whom are representative teachers of the leading colleges in this country, that, notwithstanding the vast progress made in the curriculum of many of our medical schools, there is still an utter inadequacy of clinical instruction for the majority of students. I will show at the same time that this inadequacy is not due to the want of clinical material, but to the neglect to utilize it.

Only the few fortunate victors in the competitive examinations for hospital interneship have really the clinical training necessary to make good physicians. These internes constitute a very small minority of that vast army of physicians who annually must take upon themselves the fearful responsibility of treating medically and surgically the various ills human flesh is heir to.

Of every one hundred medical students, about ten receive hospital appointments. You will probably tell me that there are any number of post-graduate schools, and you are right. The majority of these schools are really excellent, but their work and usefulness lie in another direction. They instruct the general practitioner who goes to some great medical centre every two or three years in order to brush up, and they help to educate him in special branches of medicine or surgery.

There is no want of opportunity for post-graduate instruction, and it need not be sought abroad, it can be found in our own country. But what I claim is that there is great want of clinical instruction for the medical student before he becomes a post-graduate. I say this not in criticism of any one school, but of all of them. Yet this state of affairs can be remedied, and to attain this end I beg leave to offer the following suggestions.

There should be, first, a co-operation of all the medical colleges located in one medical centre for the purpose of a general and equal utilization of all the clinical material of their city.

Second, every physician and surgeon attached to a subsidized hospital should be appointed as a clinical teacher, independent of college affiliation, and be paid a reasonable fee for his services as instructor to the students.

Third, only such men should be selected for hospital physicians as are well qualified, and who pledge themselves to perform their duties faithfully as clinical teachers.

Fourth, suppression of all the didactic lectures for second, third, and fourth year students during the morning hours, which should be devoted exclusively to clinical work.

Fifth, the obligatory presence of every second, third, and fourth year student in the capacity of senior or junior externe at the clinic, or at the daily hospital visit of his teacher.

Sixth, a record of attendance should be kept by the clinical teacher and of the work done by his externes, to be transmitted periodically to the respective college to which the student may belong. The reports should be expected to count in the annual and final examinations of the students.

As to the manner of selecting the men for the positions of hospital physicians and clinical teachers, customs vary in different countries, States, and even cities. With some medical boards, the politics; with some, the religion; with some, the social standing; with some, the affiliation or non-affiliation with a certain college; and with some, the medical qualification of the candidate—decide whether or not he shall become one of theirs.

In certain European cities, for example in Paris, the position of visiting hospital physician, surgeon, or obstetrician (médecin, chirurgien ou accoucheur des hôpitaux) can be obtained only by a competitive oral and clinical examination covering those respective branches of medicine. The board of examiners is chosen annually by ballot from among the hospital practi-

[1] Address delivered before the American Academy of Medicine, at its twenty-fifth annual meeting at Atlantic City, N. J., June 4, 1900.

tioners. This system, though excellent, might meet with some opposition in our American cities, at least at the present time. Therefore, I venture to suggest that, as requirements for hospital physician and clinical teacher, the following qualifications should be necessary: (1) Good standing as a regular and practising physician. (2) One year's experience as interne in a general hospital and one year's service as interne in a special hospital or hospitals. Five years' active work in general practice should be accepted as an equivalent to two years' interneship. (3) The approval of the candidate as hospital physician and clinical teacher by the medical board of the hospital in which he desires to work.

Each hospital should have a fixed number of clinical teachers according to the number of beds. These should be at the same time the visiting physicians, surgeons, or obstetricians, with a sufficient number of internes and externes to assure efficient service and good care of the patients.

Wherever there is an important surgical or obstetrical service, there should be an arrangement that one of the visiting surgeons or obstetricians should always be within calling distance to aid the internes in case of serious accidents demanding immediate interference. The reproach so often made, that serious operations are performed by young internes without the aid or consent of the visiting surgeon, could then no longer have foundation.

No hospital should be without the necessary bacteriological and pathological laboratory equipments, where the teachers and pupils may gather to verify clinical observations or engage in special studies.

A change of service as externe from one hospital to another could be made twice during the second, and three times during the third and fourth college years. Thus each student by the time of his graduation would have served for thirty months as externe in six to eight different hospitals; having actually spent half of his time during the last three college years at the bedside, in the operating-room, or in the bacteriological and pathological laboratories of the hospital. Whenever there is a dispensary attached to the hospital, the material it affords could also be advantageously used for clinical work by the appointed clinical teacher.

To obtain the greatest possible good out of the three years' externeship, I would divide the work as follows:

First year as junior externe, five months in the surgical service, five months in the medical service; second year as senior externe, four months in the surgical service, four months in the medical service, and two months in the obstetrical service; third year as past senior externe, three months in the eye and ear service, three months in the nose, throat, and skin service, two months in the hospital for contagious diseases of children, and two months in the service for the treatment of diseases of the mind.

The service in medicine would, of course, have to include diseases of children, with the exception of acute contagious diseases. The instructions in diseases of the eye, ear, nose, throat, and skin might be advantageously taught in the large dispensaries, and the experienced dispensary physician should also become a clinical teacher. The three years' clinical curriculum for the externe, divided in the manner I have suggested, should be obligatory for all medical students. It covers only what every general practitioner ought to know. He may specialize himself in after-years. While at the college he should learn to know how to treat all diseases which he may be called upon to attend as a general practitioner.

After having given the outlines of my plan, which, of course, only represent a rough scheme, let me substantiate what I have said in regard to the abundance of clinical material in large medical centres, and the neglect to utilize it for clinical instruction. I will cite only New York as an example; but the conditions are virtually the same in all the great medical centres of the United States.

Through the very kind and prompt replies to the letters of inquiry addressed to the superintendents of the hospitals and the secretaries of the three medical schools of the city of New York, I am able to present the following statistics: The number of medical students during the college year of 1898 and 1899 was: In the medical department of Columbia University, 801; in the medical department of New York University (former University and Bellevue colleges united) 442; in the medical department of Cornell (including matriculates at Ithaca), 241; this makes a total of 1,484.

The following is a list of the twenty-five general hospitals usually mentioned in the announcements of all three schools as an inducement to medical students to compete in the examinations for internes:

	Daily Average Number of Beds Occupied.	Number of Internes.	Term of Service.	Number of Visiting Physicians and Surgeons.
Bellevue Hospital	760	24	2 years.	32
Beth Israel Hospital	28	4	2 years.	10
City Hospital	750	24	2 years.	32
Colored Home and Hospital	240	2	1 year.	4
Columbus Hospital	80	3	18 months.	8
Fordham Hospital	40	4	16 months.	8
French Hospital	60	3	18 months.	6
German Hospital	180	6	2 years.	24
Gouverneur Hospital	39	4	18 months.	10
Harlem Hospital	40	3	2 years.	10
House of Relief	34	5	20 months.	5
J. Hood Wright Memorial	50	4	2 years.	6
Lebanon Hospital	65	3	12 months.	10
McDonough Memorial Hospital	12	0	.....	7
Mount Sinai Hospital	206	6	18 months.	10
New York Hospital	173	9	18 months.	10
Presbyterian Hospital	188	8	2 years.	7
Roosevelt Hospital	170	15	1 year.	5
St. Francis' Hospital	230	6	1 year.	7
St. Mark's Hospital	65	3	20 months.	10
St. Luke's Hospital	227	10	18 months.	12
St. Mary's Hospital	100	0	.....	2
St. Vincent's Hospital	325	6	18 months.	6
Trinity Hospital	21	0	.....	4
Woman's Hospital	90	6	18 months.	5
	4,173	158		

Thus we see that, to nearly fifteen hundred medical students, the three schools can only offer one hundred and fifty-eight places for internes in general hospitals. Of course there are numerous institutions for the treatment of special diseases, such as cancer hospitals, maternity hospitals, eye and ear hospitals, hospitals for consumptives, and so on; but the interneship in these institutions is not what the graduating student desires and needs. He wants above all the clinical training in a general hospital. He reserves the special hospital for some future date; thus, positions in special hospitals are usually sought by graduates of general hospitals, and I understand these latter are always preferred by the managers and visiting physicians of these institutions to the young men fresh from college. To complete my statistics, I will give a list of special hospitals, and the clinical advantages they offer. (See table on next page.)

The number of beds in general hospitals varies in the different institutions from seven to sixty per interne; thus some internes must certainly be overworked, while others would seem to have hardly enough to do. In special hospitals we find even a greater inequality in regard to the division of work. In some there are

ten patients per interne, in some about fifty, and among the three hospitals for consumptives one institution has three hundred and fifty beds per interne, another one hundred and twenty-eight, and one with thirty beds has no residing medical officer. The New York Foundling Hospital with its seven hundred beds has but two internes. While I am willing to concede that in a hospital for consumptives there may be no need of quite as many internes as in a hospital of equal size devoted to the treatment of general, acute, or surgical diseases, still I maintain that our knowledge in phthisiology might be materially increased if all these great hospitals for consumptives would offer a number of places for internes where the young men could carry on investigations of the most interesting kind. Tuberculosis is certainly a disease which is prevalent and important enough for such a work, and many of the clinical phases in phthisis pulmonalis will still bear some study and observation, leaving aside the vast field for research which phthisio-therapy still offers to physicians old and young alike. Lastly, the poor consumptive patients might also have a better chance for life, if they would be treated instead of being kept.

	Daily Average Number of Beds Occupied.	Number of Internes.	Term of Service.	Number of Visiting Physicians and Surgeons.
Babies' Hospital	35	0	.....	2
General Memorial Hospital	100	4	2 years.	6
Hospital for the New York Society.	184	4	2 years.	3
Loomis Sanatorium for Consumptives (City Branch)	30	0	.....	4
Manhattan Eye and Ear Hospital	48	4	2 years.	9
Mothers and Babies' Hospital	60	3	1 year.	3
New York Eye and Ear Infirmary	50	5	18 months.	23
New York Infirmary for Women and Children	60	4	16 months.	12
New York Orthopædic Dispensary and Hospital	65	2	2 years.	1
New York Skin and Cancer Hospital	45	3	18 months.	5
Nursery and Child's Hospital.	85	3	1 year.	4
Seton Hospital	128	1	Indefinite.	4
Sloane Maternity Hospital	80	4	3 months.	2
St. Joseph's Hospital	350	1	Indefinite.	12
Willard Parker Hospital	60	2	Indefinite.	6
New York Foundling Hospital	700	2	1 year.	12
	2,080	42		

You must pardon me for this little divergence from the real subject, but I consider a proper training for the future physician, in the modern ways of preventing and treating consumption, as one of the most essential factors in the solution of the tuberculosis problem. No matter how many sanatoria and similar institutions we may eventually have, for a good many years to come the majority of tuberculous patients will have to be treated at home by the general practitioner, and the better he has been prepared to do this the greater will be his power to help combat this terrible scourge of the human race.

Why our New York Foundling Hospital, with its seven hundred beds daily occupied by little waifs and homeless mothers, should have only two internes is a matter difficult to understand when we consider how great the morbidity and mortality are among the class of infants left to the public care.

I have said that in a number of general hospitals the internes are overworked, some having as many as sixty beds to look after. They have little time for laboratory work, and still less for medical reading; yet they are happy. They know they are the favored few. By cramming (pardon this expression, but it is the only one which fits the case) a great deal of theoretical knowledge, these young men were successful in a difficult competitive examination. They worked hard, and they deserve their distinction; and by and by they can put behind their names the proud title of hospital graduate. What becomes of those who fail by a few points, of the many more who could not come up, for one reason or another, for hospital examination, the college authorities do not and cannot care. These young men less favored by fortune must start out to practise as best they can with whatever clinical knowledge they may have obtained during the few hours devoted to section teaching.

Through a better utilization of clinical opportunities in all our American medical centres, all the students could receive a sufficient clinical training by serving three years as hospital externe. That there is room for every one of them I believe I am able to demonstrate. For convenience I will again refer to my New York statistics. They show that in our general hospitals each interne has to look after an average of thirty beds constantly occupied. Now, if this number of patients in each interne's care should be reduced to twenty for medical, and to even less for active surgical services, these young men would still have plenty to do; then at least two hundred and ten instead of one hundred and fifty-eight places in general hospitals would be open for competition to the graduating student, even should the present term of service of from eighteen months to two years be continued.

Reducing the term of service in the special hospitals to one year, and adding only one interne for every fifty consumptives and one for about fifty babies in the Foundling Hospital, would give us about ninety additional places. Thus we would have three hundred internes, and if each had for his assistants four externes, two seniors and two juniors, twelve hundred positions as externe would be open every year.

As has been said, the total number of medical students of the three New York medical colleges was last year fourteen hundred and eighty. I venture to say that of these not more than twelve hundred were entitled to hospital privileges; for, as we have said, only the second, third, and fourth year students should be attached to hospital service. But I am inclined to believe that if the system of an obligatory three-years' externeship should come in vogue, in a few years the hospital interne, having had already three years' service as externe, would be glad to content himself with one year's service in a general hospital, and devote his second year as interne rather to the work in a special hospital. Thus, by and by, instead of only two hundred and ten, about four hundred positions as interne in general hospitals will be open to the graduates of our New York medical schools. Besides these there are a few hospitals offering positions to internes, of which I could not report for lack of data.

With an obligatory four years' college course, an increased clinical curriculum, and a likely increase of tuition fees, there will hardly be an increase in the number of medical matriculates, and we will probably never have again four hundred graduates per year from the three New York schools; on the contrary, there are indications that we will have considerably fewer in coming years. I have learned that the graduating classes for 1901 will be a good deal smaller than were those of 1900.

The prospect that it may be possible in the near future to offer a position as interne in a general hospital for one year to every medical graduate is thus rather bright. The same prospect also holds good for the graduates from other large American medical cen-

tres. Wherever the college faculties, the hospital authorities, and the profession can come to an understanding, wherever the interest of the student as the future American physician is placed above all other interests which may concern a faculty or a hospital board, there the medical students will receive the best clinical training. But, in the mean time, let us reorganize our hospital work in all the large centres of medical education by creating a sufficient number of internes and externes, and place over them competent men as clinical teachers.

The duty of the clinical teacher should be, besides the daily talk or conference at the bedside, to give at least one clinical lecture every week, alternating with the other teachers of the same hospital. The attendance to this clinic should be obligatory for all students attached to this particular service and facultative for the pupils of other clinical teachers. The work of the interne would be what it is now, except that each would be aided by the externes, who in turn would be taught by the interne how to keep a record of the cases, how to examine urine, sputum, etc. The internes could also help the clinical teacher in teaching the students physical examination, and thus prepare themselves to be future hospital physicians and clinical teachers. In the surgical services, the externes should attend to dressing and helping the internes in the work of preparing patients for operation, taking care of instruments, and so on.

The interne like the externe should have an obligatory service in medicine or surgery during his first year, but he should have the right to devote his last year to whatever special or other work he should feel the greatest desire or need for.

Before answering the objections which might be raised to my plan, let me call your attention once more to the fact that not only would the externes be benefited thereby, but the interne and clinical teacher as well. The clinical teachers of a hospital could arrange among themselves on what days of the week to lecture, so that all internes and externes might attend.

By teaching the teacher will learn. He will not go unprepared to deliver a clinical lecture before an audience of medical students from different schools. He will be anxious to make his work as interesting as possible. He will be paid for this work, and it should be his duty to do his best. The interne, instead of eighteen months, will get five years of clinical instruction, three years as externe and two years as interne. This experience with a number of different clinical teachers can only be of vast benefit to him.

Lastly, the medical student who formerly had to take his clinical teachings in section classes, who rarely had a chance to watch a patient for several weeks in succession, will have had at the end of his three years' service as externe a wide range of clinical experience certainly equal to if not better than that which the average interne has now. The externe need no longer feel inferior to the hospital graduate. He will feel more confident to start out in life, and his future patients will be better off too. He can tell the world that he has had three years' hospital training, and feels well prepared to take upon himself the responsibilities of physician or surgeon.

Now, as to the objections: as conscientious physicians let us first see how our patients will fare under such a system. How will they like it? I venture to say they will welcome the change and like it better than section teaching. To be constantly cared for by the same two or three young "doctors" will be far less disagreeable to the patient than to be examined once or twice every week by a class of from ten to fifteen strange young men. The patients will not dread the visit and examination of these few young assistants with whom they become acquainted, as I know they often dread the arrival of the class with the teacher, who at times is not even the physician of the patient.

The increased amount of work will, of course, necessitate a four years' course perhaps of even ten months each, instead of eight or nine, and the increased fees for tuition are likely to deter a number of young men from entering upon a medical career, although in reality there should be a State appropriation for medical schools as there is for other educational institutions. Still I feel that you will all agree with me when I say that, in view of the overabundance of physicians at the present time, a decrease in the number of medical students would be rather a gain than a loss to the profession.

Another objection which will certainly be raised would come from the duly appointed clinical professors of the respective colleges; they might fear that their vocation would suffer in prestige; far from it. The importance of the chairs of clinical surgery and clinical medicine would not only not suffer from such a system, but their usefulness would be vastly increased.

All the clinical professors would have, of course, a hospital service. The hours of their clinic could be arranged so as not to conflict with the clinics of other teachers, and they would have the honor of having among their hearers not only the pupils of their own schools, but always a goodly number from other colleges.

The suppression of some of the didactic lectures will not be mourned by any student nor any well-meaning professor. I believe it is now the general opinion of modern medical educators that there are really but very few subjects in medicine which need to be taught didactically.

The last most serious objection which is likely to be raised is that the more or less numerous medical colleges in each of our great medical centres will never unite to do such harmonious work. The objectors will call my plan impracticable. Nevertheless, Paris, Berlin, and Vienna, the greatest centres of medical learning of the world, have each but one faculty of medicine; and Paris has three times as many medical students as New York.

The union of medical schools has very happily begun in some sections of the United States. We were very near reducing the number of our medical colleges in New York by one, but unfortunate inharmonious conditions created a new school alongside of the two which had united. Notwithstanding this discouraging occurrence, I am rather optimistic for the future, and when so much is at stake as the clinical teaching of the future medical men, I think the schools will have to listen not only to the needs of the student and to the demands of the profession at large, but perhaps also to the State boards which examine physicians before granting them a license to practise. These State boards have certainly done a great deal of good in raising the standard of medical education, but their examinations are of necessity all theoretical. They give no guarantee that the candidate has sufficient clinical training. Supposing all State boards should make a demand whereby the evidence of having served three years as hospital externe should be a *sine qua non* for all candidates, it would be a great step toward the clinical training of all men who would hereafter leave our colleges. But I believe that if such a movement as I have endeavored to outline before you should be inaugurated, every one of our important medical schools would be willing to respond to such an essential and useful innovation as a thorough clinical teaching of all their students.

Through an amalgamation of the clinical teaching of all schools in every large city, there may come that

glorious time for which we all so earnestly pray: Fewer and better schools, fewer and better educated physicians; one great university with one great medical faculty in each great medical centre. The standard of medical education in our own country would thus be vastly raised, and not only equal that of Europe, but become ultimately superior to that of any country in the world.

16 West Ninety-fifth Street.

DOES "CROSS-EYE" AFFECT THE GENERAL HEALTH?

By AMBROSE L. RANNEY, M.D.,

NEW YORK.

The relative percentage of the total population that is disfigured by "squint" is hard to estimate. It must confessedly be a large one. This can be easily proved to a careful observer by the inspection of any large gathering. My own leisure moments are frequently employed, while in public conveyances and social entertainments, in counting those whose eyes tend (either constantly or at intervals) to assume positions in one or both orbits that are incompatible with binocular single vision.

To the untrained observer, however, many cases of actual strabismus escape detection. This statement applies as well to medical men as to the laity. It is only when one or both eyes deviate so far from parallelism as to constitute an actual and ever-present deformity, that some medical men (who are keen observers in other lines) detect it and suggest immediate treatment for squint.

Yet it is an established and indisputable fact that eye-strain ceases, and no leakage of nervous force is created, whenever cross-eye becomes an extreme deformity and its correction seems to be the most imperative.

The anxiety of intelligent parents, whenever they bring a hideously cross-eyed child to the oculist to have the eyes straightened, is frequently much greater than the natural dread of an operation would account for; simply because their physician has unfortunately told them that "such extreme cross-eye would eventually injure the health of their child," and that they must get rid of this source of danger.

Nothing could be more ridiculous! The absurdity of such statements and views will be made apparent to the reader by subsequent physiological explanation.

The correction of a marked eye-deformity (in either a child or adult) is unquestionably most desirable. It greatly improves the personal appearance (if properly done), and it may add to the general comfort of the patient in the use of the eyes; but extreme degrees of cross-eye (in which the two eyes cannot be made to hold single images) do not (save in exceptional cases) affect the general health, or justify correction as purely a therapeutical measure.

The serious damage to health occurs only in those patients who want to be cross-eyed but can't. It occurs in those who have two eyes that naturally tend to deviate and perhaps occasionally may deviate for a time from parallelism, but which can still be used together by an unconscious effort and a large expenditure of nerve-force on the part of the patient.

Such subjects have constantly to make this unconscious and unnatural effort simply because they would "see double" if they didn't; they perhaps may or may not be conscious at times that eye-work (such as reading, sewing, shopping, attending public places of amusement, etc.) causes headache, eye-pain, or nervous fatigue; and they too often struggle on (as I personally did for thirty years until I collapsed) with an unnatural load to carry because of eye-strain that is unrecognized to-day by too many medical men, and not understood or suspected, as a rule, by the sufferer.

The eyes themselves are but two cameras. Two pictures of every object are first formed upon the retinæ and are then telegraphed to the brain cells (in the occipital lobe). Under normal conditions they are there fused into a single visual impression of which we are conscious.

In order to admit of this fusion of two visual images into one visual impression, the two eyes have to be most accurately adjusted by four pairs of straight muscles and two pairs of oblique muscles; while the one pair of muscles that controls the upper eyelids acts in unison with the other six pairs whenever the eyes are being adjusted so as to work properly together.

All adjustments of the eyes, to insure the desired effects, have furthermore to be made with marvellous quickness and accuracy.

Every possible combination of the seven pairs of muscles has at times to be specially arranged, then suddenly discarded, then a new one made, then somewhat modified (and so on *ad infinitum*) whenever the eyes are required either to follow or to be steadily directed upon the multitude of objects that are brought sudddenly or slowly to our conscious recognition through our eyes. The human mind can hardly grasp a numerical computation of these combinations of muscular efforts or the lightning changes required in seven pairs of muscles to keep the two eyes in perfect adjustment at all times and under all conditions.

Imagine, for example, one driver (or even a band of drivers) trying to direct simultaneously with seven pairs of reins seven pairs of horses in tandem through a series of most difficult and complicated evolutions at lightning speed. A slight mental conception may thus be formed of the complicated driving of the eyes; with the brain as the driver and the eye-muscles as the reins.

Again, let us take a common event as an illustration from our experiences in every-day life! We buy a new team of horses, and with a new harness (not properly adjusted to them) we start out to drive. One of the horses is soon found to be checked very much higher than the other; and the inside reins may be so short or so long that when tightened they draw the heads of the horses close together or wide apart and as a consequence compel the team to travel sidewise in order to get along under such unnecessary conditions. Every one knows that the best horses would be spoiled in a very short time by such distressing annoyances; and the trainer would be driven sooner or later to utter desperation in his vain attempts to make them work properly as a pair, if at all. The first intuitive step that would be taken (by even the merest novice) in order to remove such sources of endless irritation both to man and beast would be immediately to re-adjust the reins and checks, until the conditions became satisfactory to both the driver and the team.

Now nature often presents the same type of problem to the oculists for correction!

A pair of eyes that are simply checked too high (anatropia or anaphoria) may swing in or out constantly or occasionally as a direct result of that special type of mal-adjustment; an unnatural tension upon one or both of the inside reins (the internal recti) may make one or both eyes turn in (esotropia); a shortness of the outside reins (the external recti) may give constantly or at times a divergent squint (exotropia); the upper eyelid may droop (constantly or at intervals) purely as a result of some mal-adjustment of the eyeballs themselves; and a tendency to turn or actual turning of both of the eyeballs downward (kataphoria or katatropia) may create apparent distortions of the eyes in other directions than the one actually at fault.

Frequently, as a result of some abnormal adjustment of the eye-muscles, certain peculiar attitudes of the head of the patient become a fixed habit; because, by simply altering the position of the head, difficulties experienced in maintaining binocular single vision upon the proper plane may be modified unconsciously and occasionally overcome entirely.

In my recent work, entitled "Eye-Strain in Health and Disease,"[1] I devote some pages to this interesting field in diagnosis. I show in those pages that a marked and constant elevation of the chin means that the eyes are adjusted for too low a plane; and that a marked depression of the chin upon the chest, with a protrusion of the forehead and a persistent stoop of the shoulders, almost always indicates that the eyes are adjusted for a plane higher than the horizon.

These types of patients sometimes have a very marked apparent "squint" either inward or outward; yet an operation performed upon an internal or external rectus in a case of these peculiar types would not cure the squint or rectify the unnatural posture of the head.[2]

The principles involved in the surgical relief of cross-eye are fortunately better understood to-day than they were in the past. It is safe to assert that in no field of surgery has there been a larger percentage of failures in the past than in the treatment of squint. The remarkable improvement in the results now obtained (after surgical attempts to rectify the various types of this deformity) has been due largely to the more careful study of the eye-muscles by the tropometer and the phorometer. Personally I should not deem any one to-day competent to treat scientifically a case of strabismus unless he was well versed in the use of these modern instruments.

Red-Glass Test.—One recognized clinical distinction between actual squint and simple insufficiency of ocular muscles is this: In squint, when a plain red glass is held before either eye of the patient and the patient is instructed to gaze with both eyes open upon a candle-flame at the distance of twenty feet from the eye, two images of the candle are seen (a red and a white image).

The relative position of the double images to each other (when unconquerable diplopia is found to exist) is the guide to the oculist in detecting the type of squint; and the strength of prism required to enable the patient to fuse the double images is an approximate way of determining the amount of the "manifest" tendency of the eyes to cross.

In other words, the presence of diplopia (double vision), when a red glass is held before either eye, is a diagnostic sign of squint.

But do all patients with squint see double images with or without the red-glass test? By no means! In fact, it is very uncommon in testing patients with extreme cross-eye to get them at first to see the double image. The reasons for this difficulty are either that patients of this class have learned to suppress visual perceptions in one eye when the other is fixed upon some object, or that the double image is too far removed from the normal field of vision to be recognized without long-continued practice.

I have known patients who had for years suppressed visual images on account of squint to practise for weeks with a red glass before they could simultaneously see the image of a candle-flame with both eyes. I commonly teach such patients to do this by having them fix one eye upon the candle-flame while the other is shielded with a card and covered with a red glass. I instruct them to look intently at the candle-flame and to endeavor to detect the colored candle image when I remove the card from in front of the eye that has the red glass before it.

After repeated attempts, most cross-eye patients can be made to recognize double images by this method; but occasionally a strong prism has to be used in connection with the red glass to bring the double images within the normal field of vision before the patient can be taught to use both eyes simultaneously while tests are being made.

Exclusion Test.—A second point of great value in the preliminary investigation of cross-eye is the employment of the so-called "exclusion test."

The patient is instructed to look intently with both eyes open at a candle-flame twenty feet at least from the eye, while a card is held as a shield over one eye and shifted from eye to eye alternately so as to exclude either the right or the left visual image. While either eye is shielded the observer notices carefully how that eye deviates from parallelism with its fellow when the card excludes its visual image; and the observer also notes with care in what direction the same eye moves when the card is shifted to cover the opposed eye. If, for example, the right eye deviates upward and outward behind the shield and jumps downward and inward when the card is shifted to cover the left eye, and the left eye deviates downward and outward behind the shield and jumps upward and inward when the opposed eye is covered, the observer knows that right hyperphoria exists with exophoria (or that the right eye tends to assume the highest vertical planes and that both eyes tend to deviate outward). Prisms are now placed before the eyes to correct properly the abnormal jump of the eyes, and the extent of the manifest squint can usually be approximated in this way.

If both eyes jump downward when the card is shifted, both eyes are too high; if both jump upward under like conditions, both eyes are too low; if both simply jump inward, the eyes are in vertical balance but deviate outward; if both eyes jump outward, the case is one of convergent squint.

A third preliminary step in the examination of cross-eye patients is to determine the refraction of each eye with certainty, and if markedly abnormal to correct the refraction with glasses for some weeks before any positive conclusions are formed or advice is given regarding the correction of the squint.

Refractive Tests.—Without thorough tests for abnormalities of refraction, no muscular tests are positive and many are often misleading. A mydriatic ought always to be used.

I recall a case in which a physician lately brought a terribly cross-eyed lady to my office for operation. Her disfigurement was extreme. She was found to have marked astigmatism and unequal refraction. The prescribing of proper glasses for constant wear for one month was advised. At the end of a month all symptoms of cross-eye had totally disappeared, and by careful tests no abnormality of the eye-muscles could be detected by me. An operation on this patient would have been a sad mistake.

Results of Eye-Strain.—The amount of nervous disturbance that may be created by eye-strain in those subjects that are on the border-line of "squint" without actual deformity is sometimes extreme.

There is hardly a nervous disease of the functional type that cannot be induced by this cause. Patients who suffer from headaches, neuralgias, chorea, epilepsy, nervous prostration, and even insanity from this reflex cause are unquestionably encountered. This is no idle dream, nor is the statement made from rash enthusiasm. I might quote from my work on "Eye-Strain" (previously referred to) many cases that

[1] F. A. Davis Co., Publishers, Philadelphia, 1897.

[2] Dr. George T. Stevens considers the conditions known as "kataphoria" or "katatropia" as predisposing causes to lung diseases and chronic inflammatory conditions of the respiratory tract; because depression of the chin tends to compress the larynx, and the stooping shoulders contract the chest and interfere with its proper expansion.

clearly demonstrate the accuracy of my statements to all unprejudiced minds.

I owe personally to this great discovery in medical science my ability to practise my profession the past ten or twelve years; and the gratitude manifested by others who have been restored to perfect health by eye-treatment after all other avenues of escape seemed closed to them, does not exceed my own.

Cases Reported.—The four cases of squint whose clinical histories are given in connection with these preliminary remarks are peculiarly interesting examples of what can be done toward restoration of single vision by modern methods.

Case I. presented one of the most difficult eye-problems to correct that I have ever yet encountered. The combination of 25° of vertical squint with 14° of crossed diplopia (which this patient disclosed at the first examination) is not one from which most oculists would hope to obtain binocular vision and perfect muscular balances.

The extreme nervous disturbances caused by the eye-defects seemed to me, at first, as totally inconsistent with so marked a degree of diplopia. I attribute them now to the fact that this patient must have at times made great efforts to obtain single vision and been partially or completely successful. He always had carried his head on one side to an extreme degree. This tended to aid him in overcoming his vertical defect. Had he suppressed images, he would not have been conscious of transient diplopia or been nervously afflicted. One thing is certain, viz., that the establishment of binocular vision at all points has for the past four years totally arrested his nervous symptoms, which were the cause of great suffering in the past.

Case II. illustrates well the fact that an extreme maladjustment of the ocular muscles combined with unequal refraction can cause no nervous disturbances. A part of the parental eye-defects was, however, transmitted to his children; to a less degree, but sufficient to entail increasing eye-strain and to induce very serious nervous results.

The two sons who developed epilepsy (and who were cured by me through eye-treatment alone) inherited from the father just enough of his eye-defects to make the maintenance of single vision difficult and to entail upon them a constant waste of nerve-force—hence their epilepsy.

The daughter (who for years was a victim to extreme and alarming nervous prostration) recovered her health completely after I rectified the mal-adjustment of her eye-muscles and gave her proper glasses. She also owed the cause of her nervous collapse to the inheritance from her father of only a portion of his extreme eye-defects.

The father had squint, yet no nervous disturbances; the children were practically on the border line of squint, without disfigurement, and were nervously afflicted.

Case III.: This remarkable case of sudden nervous collapse, associated with a total inability to use the eyes or to hold single images, teaches some valuable lessons to those not familiar with the results of eye-strain.

Many victims to congenital eye-strain, who have for their entire life been unconsciously on the verge of diplopia and who have in consequence been making constant and almost superhuman efforts to see single, often lose control of their eye-muscles suddenly and sometimes do not ever regain their ability to overcome their congenital tendency to "cross-eye." It is not necessarily paresis; nor does it usually mean the development of brain-trouble. It is more apt to be the result of simple nervous exhaustion, and a rebellion (as it were) on the part of nature against trying to use a pair of eyes together that are not properly adjusted for single vision.

When the reins that drive such eyes are readjusted properly by the oculist, and when nature feels assured that all former difficulties of adjustment are permanently removed, slowly the ability to use the eyes together is in most instances re-established.

In this particular instance, the first tenotomy (not performed by myself) corrected a part of the muscular mal-adjustment and for a short time re-established single vision. Soon a return of the diplopia occurred, and the patient became alarmed and the oculist doubtful about further operative work.

Because the difficulties to be surmounted and the various steps required were not fully understood by the patient he naturally regarded the first operation as a dismal failure—when, in reality, it constituted but the first step toward a re-establishment of muscular equilibrium in the orbits. He lost confidence in his oculist simply because the oculist himself had not apparently a clear conception of what he had to meet; and because he failed to state in advance to the patient his exact line of procedure, which probably was not very clearly defined even in his own mind.

Had the oculist used the exclusion test, together with phorometer and tropometer records, he would have known early that one eye was much higher than the other and that both eyes diverged; he would have been able to state to the patient before operation that several graduated tenotomies might be demanded to insure permanent relief; he could have explained in advance to the patient just what each proposed step would accomplish toward the desired end; and he would have been able to carry his work along to completion with the full confidence and support of his patient.

The tropometer would have told the oculist that the case was not one of paresis. The history of the case did not justify either the suspicion or diagnosis of brain-disease. The sudden development of diplopia pointed naturally to a high degree of "latent heterophoria." In all human probability such an amount could not be overcome by one graduated tenotomy; and the patient should have been prepared early by intelligent explanation for probable recurrences of his symptoms from time to time until the muscular mal-adjustment was satisfactorily corrected.

The perfect re-establishment of control of the eyes for reading, book-keeping, and business pursuits in fine machine work, and the total disappearance of double vision after three subsequent graduated tenotomies had been performed by myself, demonstrate clearly that the first operation performed upon this patient was not a failure. It simply corrected a small part of the mal-adjustment of the eyes. It enabled the patient to see single images for a time only—but the hyperphoria and exophoria that still remained uncorrected eventually caused a return of the diplopia.

Case IV. illustrates some important clinical points that aided materially in restoring an apparently hopeless condition of the eyes to the normal condition; in spite of the fact that a persistent diplopia had interfered seriously for years with every pleasure and all use of the eyes.

When I first saw her and tested her eyes, this patient presented some eye-problems that were extremely puzzling to me and which for a long interval seemed discouraging both to the sufferer and myself. A perfect recovery, however, followed after two years of travel. Prior to this trip I had by graduated tenotomies placed the eyes where the patient could hold single binocular vision for short periods of time; but it took over six months of travel before any satisfactory use of the eyes became possible, and one full year before the patient could read with ease and comfort.

After a perfect control of the eye-muscles in their

new adjustment had once been acquired by this patient, no return of diplopia either at near or distant objects has ever occurred.

The following table will explain the meaning of certain terms used in the published records of individual cases and also in subsequent pages of this article:

Terms related to the focus of the eye (*refractive terms*).

- HYPERMETROPIA (*far-sightedness*). A *shallow eye* (from the front to the back), causing an imperfect focus of objects.
- MYOPIA (*near-sightedness*). An *elongated eye* (from the front to the back), causing an imperfect focus of objects.
- ASTIGMATISM. An *irregularly-curved cornea* or *lens*, causing distortion of images on retina.
- EMMETROPIA. A *perfectly constructed eye*.

Terms related to the muscles which move the eyes (*muscular terms*).

- ESOPHORIA. A tendency of one or both eyes to deviate toward the nose.
- ESOTROPIA. An actual turning of one or both eyes toward the nose (*convergent squint*).
- EXOPHORIA. A tendency of one or both eyes to deviate toward the temple.
- EXOTROPIA. An actual turning of one or both eyes outward (*divergent squint* or "wall-eye").
- HYPERPHORIA. A tendency of one eye to rise above the level of its fellow.
- HYPERTROPIA. An actual turning of one eye above its fellow (*vertical squint*).
- ANAPHORIA. A tendency of *both eyes* to assume too high a plane.
- KATAPHORIA. A tendency of *both eyes* to assume too low a plane.
- HETEROPHORIA. Abnormal adjustment of the eye-muscles.
- ORTHOPHORIA. Normal adjustment of the eye-muscles.
- ADDUCTION. The power of the internal muscles of the eyeballs. *It varies in health between 25 and 60.*
- ABDUCTION. The power of the external muscles of the eyeballs. *It should be 8 in health.*
- SURSUMDUCTION. The power of the vertical muscles of the eyeballs. *The right and left should be alike.*

Various forms of glasses employed by oculists.

- SPHERICAL. Ground upon a *convex or concave sphere*. Used to correct hypermetropia and myopia.
- CYLINDRICAL. Ground upon a *convex or concave cylinder*. Used to correct astigmatism.
- PRISMATIC. *Two plane surfaces of glass meeting at an angle*. The thick side is termed the base of the prism. Used to relieve mechanically errors of adjustment of the eye-muscles.

CASE I.—Mr. M——, aged thirty-six years, married, lawyer. Referred to me May 10th, 1892, by Dr. H. E. Hayd of Buffalo, N. Y. Family history not known.

History of Case: This patient had always been an intensely nervous man, with many choreic symptoms. For many years he had done a large law business; although suffering extremely from nervousness, irritability of temper, confusion of head (with slight headache occasionally), inability to use his eyes steadily, and at times almost complete nervous collapse.

When he came to me he complained chiefly of his inability to use his eyes or to concentrate his mind on his business without becoming extremely nervous. He was also troubled with burning and watering of his eyes.

He was so nervous that he would nearly jump from his chair if by accident I touched his head or even his hair with my hand while testing his eyes. Sudden noises, such as the ringing of my door-bell, also caused a nervous jump. He had been absolutely unable to play tennis or any similar game, as he could not concentrate his vision on the ball without causing extreme nervousness and distress in his head.

Eye-Defects: On the first examination this patient had $\frac{20}{20}$ vision in each eye with or without the glasses he was then wearing, which were O.D. + 1.00, O.S. + 0.75. He had also a diplopia (with a red glass) corrected by 25° of left hyperphorial prism combined with 14° of exophorial prism.

Under homatropine, he had vision of $\frac{20}{15}$ in each eye with + 0.50 c. axis 90° added to his hypermetropic glasses; but his muscular tests were the same as before.

Treatment and Results: The correction of this extreme heterotropia required a number of tenotomies, extending over a period of two years. The left eye was lowered, the right raised, and both eyes let in by graduated tenotomies performed upon the left superior rectus, the right inferior rectus, and both externi. The full correction was also given for his refraction.

The result of these operations was the establishment of almost absolute orthophoria. I have tested his eyes once or twice a year for the past four years; and he invariably shows no hyperphoria and an exophoria of from $\frac{1}{4}$° to 1°. His adduction is 30°, abduction 6°, right and left sursumduction 4° each. From his tropometer tests, it will be seen that in spite of several graduated tenotomies his rotations are about normal. They are the same in each eye, upward 30°, downward 50°, nasal 50°, temporal 50°. The vision of each eye with his refractive correction is $\frac{20}{15}$. He now uses + 1.25 s. over his distance correction, for reading.

The improvement in the physical and nervous condition of this patient is as great as the remarkable improvement in his eye conditions would lead any one to expect. He has lost all of his nervousness; has gained twenty-five pounds in weight; attends to a constantly increasing law practice with perfect ease; and uses his eyes with absolute comfort under all conditions.

CASE II.—Mr. P——, aged fifty-five years, married, banker.

Family History: Nothing is known of the patient's ancestry. Two of his sons had epilepsy and have been cured by eye-treatment under my hands; one of them having passed over five years and the other over three years without an attack since their eye-muscles were rectified. One daughter of the patient had complete nervous prostration for five years, and was kept in Europe under professional care for that condition without benefit. Subsequently she was also restored to perfect health by me through eye-treatment. The mother of these children had orthophoria; so that all the muscular anomalies found in them were evidently inherited from the father.

History of the Case: This patient had always been a remarkable rifle-shot and had won great distinction during the War of the Rebellion as an officer in the sharpshooting corps. In the performance of feats of marksmanship only one eye is used; hence the extreme strabismus of the patient and the bad refraction of one eye were no disadvantages to him in the use of the rifle. In fact, his extreme devotion to duck-shooting and its out-of-door life had probably prevented many ills which his eye-strain might have brought upon him, had his life been devoted exclusively to indoor occupation. For some years before he placed himself under my care, he had a pair of glasses which he used to amuse himself with at times by reversing them, when he wished to use them at the reading-point; thus bringing the distance glass of the poor eye into use as a reading-glass for the good eye, and throwing the poor eye entirely out of use while reading.

For many years prior to my seeing him he had frequent and unexplainable attacks of aggravated urticaria. These attacks came on when he was nervously run down, and often confined him to the house for several days at a time. They did not seem to be dependent upon any errors of eating or drinking, and were most puzzling to all of the physicians that were consulted about them. Throughout his entire life he was a rather nervous man with an enormous amount of physical and mental energy; but his powers of nervous endurance seemed to be almost unlimited, except when these peculiar conditions of the skin would develop. He placed himself under my care, after I had cured three of his children of serious

nervous troubles, rather for the purpose of enabling him to use his two eyes together than for the cure of any special nervous ailment.

Eye-Defects: This patient at his first visit showed the following refraction: O.D. V. $\frac{20}{20}$ with + 4.00 s.⊖ + 0.50 c. axis 180°, O.S. V. $\frac{20}{20}$ with + 1.75 s. His muscular tests (with the above correction on) were: right hyperphoria 5°, esophoria 3°, adduction 18°, abduction 7°, right sursumduction 13°, left sursumduction 2°. He had vertical diplopia with a red glass. He required + 2.50 s. added to his distance glasses for reading.

Treatment and Results: A full correction was at once given for his refractive error, and it has never been found necessary to change this glass, although I have tested him carefully once or twice each year since. + 2.50 was added to his distance correction for reading, and later this was increased to + 2.75. These glasses were worn for some months to see whether his hyperphoria would disappear after the correction of his unequal refraction, as is sometimes the case. In this instance, however, the hyperphoria proved to be genuine, and he showed the same muscular tests as when the glasses were first given. Accordingly a 3° prism, base up, was combined with his left lens and worn for a few months. A tenotomy was then performed on the right superior and on the left inferior rectus. Since the last operation he has never shown any hyperphoria, and his esophoria has fluctuated from 0° to 1°. He shows adduction 23°, abduction 8°, right and left sursumduction 6° each.

Since the establishment of binocular vision by tenotomies and the correction of his unequal refraction by glasses, this patient has noticed a very decided improvement in his general nervous tone, an ability to bear strain with much less fatigue, and a wonderful sense of comfort in his eyes that he had never before experienced. Strange as it may seem, he has no attacks of urticaria that formerly were the pest of his life. I interpret their absence rather as the result of improved nervous tone and stronger digestive functions than to any possible eye-reflex; although there are too many skin conditions that are unmistakably traced to nervous origin to justify us in ignoring altogether the eye-reflex.

The wife of this patient stated not long ago, while in my office, "that she could see a very great change for the better in her husband's health in a thousand little ways, since his eyes were treated."

One interesting feature in connection with this case is this: that the extreme difference of refraction in the two eyes, which for over fifty years had been uncorrected by glasses, and the extreme strabismus of the patient had unquestionably prevented much more serious ills of a nervous type than a less degree of heterophoria had produced in his children.

Case III.—Mr. S——, aged twenty years; single; student.

Family History: Both parents are living and well. No hereditary tendencies to nervous diseases or phthisis exist.

History of the Case: This patient was not a very robust boy and suffered considerably with headache, nervousness, and general debility. He never had any acute nervous disease up to June, 1897. He was at that time a student at a prominent university, and broke down completely with headache, nervousness, and absolute inability to use his eyes (with diplopia at times).

He was put under the care of a prominent oculist in New York City, who found exotropia 18° and right hypertropia 6°. A well-known physician, who was called in consultation, diagnosed "ocular paresis having its origin in the effects of the diseases of childhood." He had had meningitis when one year old. He was put on strychnine at once and atropine was dropped in his eyes, but he did not improve.

In December, 1897, the left externus was divided by the oculist previously referred to. He regained single vision, and improved so rapidly in general health and use of his eyes that he returned to the university.

In March, 1898, he again broke down with nervous prostration, headache, and double vision. He returned to the oculist who treated him before, who referred him to me for further treatment, as the case presented some problems that puzzled him and others who had seen the case.

Eye-Defects: When he first came to me he was wearing constantly a full atropine correction for his refraction, *i.e.*, O.D. + 0.25 c. axis 90°, O.S. + 0.50 c. axis 90°. His muscular tests were: Right hyperphoria 4°; exophoria 11°; adduction 16°; abduction 17°; sursumduction, right 4½°, left 3°. His rotations with the tropometer were about normal, showing that no paresis existed in any ocular muscle.

Treatment and Results: A tenotomy was at once performed on the right external rectus muscle, and a few weeks later a second tenotomy was done on the same muscle. A 4° right hyperphorial prism was then combined with his cylinders for constant wear.

With this correction he had single vision and began to use his eyes with comfort and was free from headache. Within a few weeks he engaged in the study of his father's business, which was the manufacture of machinery, and used his eyes for fine work seven hours a day without the return of any nervous symptoms. In September, 1899, I performed a tenotomy on the right superior rectus and removed the prism from his glasses.

He is still working very hard and remains perfectly well, with ability to use his eyes steadily for seven or eight hours a day.

His muscular tests are: Adduction 21°; abduction 13°; sursumduction, right 9°, left 5°; exophoria ½°; right hyperphoria ¼°. With the Maddox rod he at times shows more muscular defect, both exophoria and hyperphoria, and it is probable that he has more latent muscular trouble; but as he is doing his work comfortably and holding single images, it does not seem wise to push the correction of his eye-muscles any further at present.

Case IV.—Miss W——, aged thirteen years.

Family History: Both parents are living and well. One sister had severe headaches, which were relieved by my prescribing hypermetropic glasses.

History of the Case: This young lady was sent to me nine years ago suffering with headache, inability to use her eyes, and extremely annoying double vision.

Eye-Defects: This patient had myopia of three diopters, for which she was wearing correcting glasses. At the first visit she showed crossed diplopia of 14° with the red glass and at times showed also some left hyperphoria.

Treatment and Results: The treatment of this case required a great deal of operative work on the eye-muscles. Within one year both externi were divided freely, both interni were advanced, and graduated tenotomies were performed on the left superior and right inferior recti.

By these steps all of the hyperphoria was corrected, and she showed but two or three degrees of exophoria; but in spite of the close approach to orthophoria, she was unable to hold single images for more than five or ten seconds at a time. Static electricity, which had been applied at times to the internal recti during treatment, was now continued daily for several weeks until she was able to hold single images for forty-five seconds at a time. The diplopia was then only noticeable when looking at a very small bright object, as a candle-flame used in testing.

She then was obliged to leave for Europe for two years. On her return she showed no hyperphoria or exophoria, adduction 28°, abduction 8°. Prismatic exercises were used for two weeks, and her adduction increased to 45°.

Ever since then she has been using her eyes very hard. with no discomfort and with no headache. She has had no return of diplopia.

Summary and Conclusions.—1. A small percentage of subjects in whom cross-eye exists (even to a degree of extreme deformity) owe their existing disfigurement entirely to errors of refraction. Proper glasses alone will correct the disfigurement of such patients.

Extreme nervous phenomena may coexist in this type of case with the cross-eye, and disappear entirely when the refractive correction is properly made by glasses.

2. Extreme and constant disfigurement from cross-eye, which does not prove to be the result of refractive errors, does not as a rule entail eye-strain or tend to create reflex nervous disturbances.

3. Those who suffer only occasionally from cross-eye and at other times show no cast are peculiarly liable to reflex nervous diseases.

These subjects are constantly on the border line of double vision, and are wasting nervous force incessantly in their unconscious endeavors to maintain binocular single vision. The red-glass test and the exclusion tests are of great diagnostic value with such patients.

4. Extreme cross-eye inward or outward (convergent or divergent squint) is occasionally due to the fact that both eyes are adjusted either too high or too low in the orbit (anaphoria or kataphoria). This is a clinical fact that has been unrecognized by oculists until of late. It is a most important point to decide by the aid of the tropometer prior to operative interference in all cases of lateral squint.

5. Some subjects are unconsciously able to adjust for very high degrees of "latent" squint, and actually to maintain binocular single vision most of the time. The red-glass test in such cases usually develops unconquerable diplopia at once.

Severe nervous troubles are very common in patients of this type. The extreme mal-adjustment of the eye-muscles is very apt to be overlooked and remain uncorrected. This is because the squint is not constant, and when present is too often attributed solely to physical debility, excessive use of the eyes, etc.

6. The "phorometer" and "tropometer" are often essential to the proper recognition of the causes of cross-eye and the particular muscles at fault in individual cases.

7. To those of the profession who have not a "phorometer" or a "tropometer" the employment of the "Maddox rod"[1] and the red glass will sometimes furnish extremely valuable information regarding the causation of reflex nervous disturbances from eye-strain.

Patients who are on the border-line of squint will very often reveal their existing eye-strain at once (in the form of unconquerable diplopia) when the red-glass test alone is made.

I recall a rather amusing instance when a brother physician of this city, who had broken down completely in a nervous way and been for years under the care of an oculist of national reputation, resented as a serious affront to his vanity my assertion "that he was and always had been cross-eyed at times." I offered to prove it, and when a red glass was handed to him subsequently in my office to use as a test for his own personal satisfaction, he found that unconquerable double vision existed. He was operated upon immediately for his squint. He recovered his health at once, after his eye-strain was arrested. This sufferer had previously been wearing only a prism of two degrees for his reading, when he in reality had been unconsciously struggling for his entire life to overcome his tendency to cross-eye.

8. The "exclusion test" (previously described) is of great value in cases of squint. It is often extremely difficult and sometimes almost impossible to teach patients afflicted with cross-eye to abandon their unconscious habit of suppressing visual images. The "exclusion test" then becomes the chief reliance of the oculist in determining both the form and degree of mal-adjustment that exists, and in many instances which operative step to take first.

9. When vertical and lateral squint coexist, it is usually wise to correct the vertical mal-adjustment (either entirely or in part) prior to operation upon the lateral muscles.

There are enough exceptions to this rule, however, to make it wise for the oculist to study the effect of prisms upon his squint cases (prior to operative treatment) for a sufficient length of time to observe their influence. It is also advisable, as a rule, to get daily tropometer measurements for a week or two in cases of this peculiar type. Too much haste in operative procedures for the correction of combined lateral and vertical squint is apt to lead to unsatisfactory results.

I have had to do many advancements in my office, simply to correct mistakes made by others because of undue haste in undertaking the surgical correction of a complicated case of squint.

10. The old methods employed in operating for cross-eye have been so modified since the discovery of cocaine that the most extreme deformities can be rectified to-day without pain and even with no confinement to the house.

Formerly, the patient was obliged to take a general anæsthetic (chloroform or ether); the surgeon had usually to have two assistants, one to administer the anæsthetic and the other to assist in the operation; antiseptic dressings were applied to the eye, because it had a large conjunctival wound; and the patient was prevented from following his customary business pursuits for several days at least. To-day, a few drops of cocaine solution are dropped into the eye at intervals of a minute or two until the eye has entirely lost all sensibility to pain; the opening made through the conjunctiva is so small as to make the tenotomy almost a closed wound; the tendon is "buttonholed" through this small conjunctival opening; the patient is able to aid the operator by fixing vision steadily upon some designated point that puts the desired muscle on the stretch; the amount of tension relieved by the operation can be measured immediately (because the patient is conscious, not being under a general anæsthetic); and, finally, no surgical dressings are required after the operation, nor is it necessary to confine the patient to the house.

It certainly robs an operation of all its terrors when it is possible to correct extreme deformities by so simple and painless a method; to avoid all interruptions of business pursuits; to escape all danger of subsequent inflammation by having practically a closed wound; to be able to measure the results of the operation at the time; to enlarge the buttonhole in the tendon at one sitting as often as seems imperative: and to avoid the natural dread of taking ether or chloroform, with its possible dangers, loss of consciousness, and subsequent nausea and vomiting.

I have frequently operated upon young cross-eyed children in my office while I talked with them about the prospective pleasures or awards offered them by their parents in case they earned them by good behavior while the operation was being performed.

[1] A little device that can be carried in the pocket and that costs but a trifling sum.

11. In conclusion, I would impress upon my readers that a scientific correction of most cases of cross-eye takes more time than is usually allotted to such cases.

To pick up the tendon of an eye-muscle on a strabismus hook without any special study of the existing conditions, and to divide it completely (as has been done for years by many oculists for the relief of squint), is to-day a very crude and practically an obsolete method of procedure with those who aim at attaining orthophoria.[1]

Simply to get an improvement in personal appearance (that must of necessity be more or less uncertain, when operative procedures are attempted on so crude a basis) is not all that should be sought for by oculists.

Any person who has never had binocular single vision (in consequence of cross-eye) is peculiarly liable to be greatly annoyed by double images whenever the eyes are brought approximately but not quite to their normal position in the orbits by operations upon the eye-muscles originally at fault. The eyes will possibly look better to the casual observer than they did before the operations were performed; but the patient may become a sufferer from double vision and also from certain nervous disturbances never experienced while disfigured by cross-eye.

For this reason, if for no other, it is vitally important to endeavor to get as exact and perfect an adjustment as possible, and to save the patient many annoyances and possibly a nervous break-down that are apt to be entailed by imperfect operative work and the consequent eye-strain in overcoming a tendency to diplopia that never before existed to the same degree.

345 Madison Avenue.

REPORT OF A CASE OF PORRO-CÆSAREAN OPERATION.[2]

By WILLIAM J. GILLETTE, M.D.,

PROFESSOR OF ABDOMINAL AND CLINICAL SURGERY, TOLEDO MEDICAL COLLEGE; SURGEON TO ROBINWOOD HOSPITAL, TOLEDO, OHIO.

The case of Porro-Cæsarean section I have to report is the sixth successful one, so far as I have been able to learn, in this State (Ohio). The first one was performed by Dr. J. F. Baldwin, of Columbus, on July 12, 1889, upon a rachitic dwarf with contracted pelvis. He saved both mother and child. On December 11, 1894, Dr. Hunter Robb, of Cleveland, operated, saving both mother and child. His case was one in

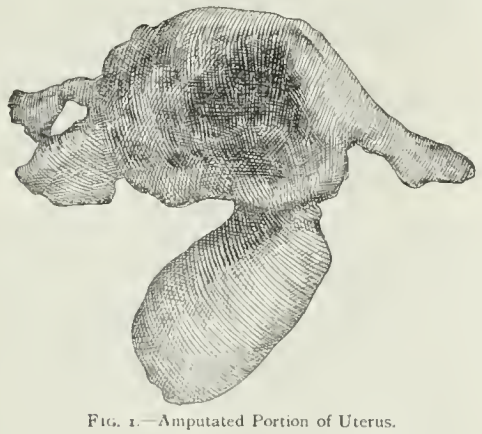

Fig. 1.—Amputated Portion of Uterus.

which the pelvic outlet was obstructed by a fibroid tumor arising from the cervix. On May 22, 1896, Dr. Edwin Ricketts, of Cincinnati, saved a mother. The obstruction was also a fibroid of the cervix. The same year a homœopathic physician in Toledo, Dr. O. Reese, operated, saving both mother and child; the obstruction was a specific contraction of the vagina. On April 24th of the present year Dr. George Crile, of Cleveland, saved mother and child in a case of con-

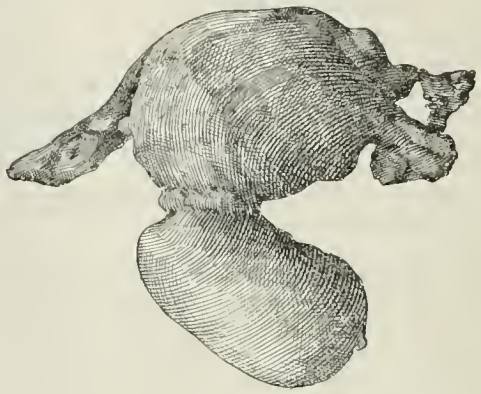

Fig. 2.—Fundus of Uterus with Tumor Attached.

tracted pelvis. All the cases here mentioned, except those of Drs. Robb and Crile, were done by fixing the pedicle in the lower angle of the incision.

The history of my case is briefly as follows: I was called to Findlay, Ohio, October 21st, last, by Drs. George F. Suker of Toledo, and J. P. Baker of that city, to see in consultation a married woman, a primipara, who had been in labor at full term, when I reached her, about forty-eight hours. Her family history has no bearing upon the case. Her father died at the age of sixty-two years, of a probable perforative peritonitis. The mother is living, aged sixty-two years, and well. One brother died in infancy. One brother is living, at the age of twenty-nine. No hereditary disease could be traced. She began to menstruate at seventeen years of age; menstruation was always regular after the first year, but painful, never profuse. Ten months since, her family physician in Gambier, Ohio, discovered a small tumor on the anterior wall of the uterus; prior to this, she supposed herself to be perfectly normal. Aside from an occasional pain in the back, her pregnancy gave her no discomfort.

On examination, a fibroid tumor, the size of a child's head, was found so completely blocking the pelvic outlet that it was with difficulty that the cervix could be reached at all. The contractions of the uterus apparently had so impacted the tumor in its position that all attempts at raising it out of the pelvic cavity, in order that the child might pass, were futile. It was so fixed that I could not move it at all.

The gravity of the condition was at once recognized, and immediate operation was urged by both Dr. Baker and myself. To this the patient and friends readily assented, when she was at once made ready, placed aboard a midnight train, and taken to Robinwood Hospital in Toledo, arriving there safely at about two o'clock in the morning. It was not, however, until ten o'clock, or about sixty hours after labor had commenced, that I operated. In the mean time Dr. C. A. Kirkley, of Toledo, was called in consultation.

Though labor had been in progress for sixty hours, and the waters had long since drained away, the patient when finally placed on the operating-table was in good condition, with a pulse of 68, a normal temperature, and no sign of exhaustion whatever. In the presence of a number of medical gentlemen, I operated, opening the abdomen by a median incision, when the relation of the tumor to the uterus could be clearly made out, it being connected to it on the posterior wall near the fundus by a pedicle the size of a wrist.

The tumor occupied such a position and was so im-

[1] See table of terms on preceding page.

[2] Read before the Northwestern Ohio Medical Association, at its meeting in Findlay, Ohio, December 7 and 8, 1899.

pacted in the pelvis that it was quite impossible to deliver either it or the uterus before the child was removed. It was impossible to do otherwise than incise the uterus *in situ*. It was also quite impossible to throw a rubber ligature around the cervix for the purpose of controlling hemorrhage.

The uterus was now opened anteriorly and a fœtus weighing seven and three-fourths pounds removed. The umbilical cord having been clamped and cut, the child, in good condition, was taken in charge by the nurse. The hemorrhage from the uterus was in the mean time controlled by my assistant, Dr. H. L. Green, who compressed with his hands the incised walls of the uterus against the abdominal walls. The uterus did not properly contract, and whenever the compression was relaxed in the least the bleeding was furious.

I removed the placenta at once without difficulty, but its removal was followed by profuse hemorrhage, which was only in part controlled by packing large sponges firmly into the uterine cavity.

The tumor was now with considerable difficulty enucleated from its position in the pelvis, where it had acquired rather extensive adhesions, and it, together with the uterus, was brought out of the abdomen. It was now for the first time possible to throw a rubber ligature about the cervix, which was done, completely controlling hemorrhage, and the uterus was amputated.

After making the pedicle as small as possible it was placed in the lower angle of the incision, the peritoneum was stitched about it, and two hysterectomy pins were inserted to hold it in place. Had I the same operation to perform again, I would most certainly drop the pedicle or do a panhysterectomy; though this patient did excellently with the method described. The abdominal cavity was now well washed out with decinormal salt solution and closed with interrupted deep silkworm-gut and buried catgut sutures.

The patient was placed in bed with a pulse of about 80. The time of operation was forty-five minutes. The pedicle came away at about the end of the second week. The rubber cord was removed at the end of the fourth day. For a few days after the pedicle sloughed, solutions used for vaginal douches came out through the opening left by it, but this soon closed, and the abdominal incision healed perfectly. At no time did the patient's pulse reach 100; 88 was the highest recorded, and the highest temperature was 101¼° F.

For a few days after the operation the patient suffered from a cystitis, which, however, entirely subsided after washing out the bladder a few times with a carbolic-acid solution. As soon as the patient came well out from the anæsthetic the child was placed at the breast. It has since grown nicely. At no time has it been given anything but the mother's milk.

Gonorrhœa in its Relation to Insurance.—D. D. G. Hall says that if an examiner meets with an applicant for insurance suffering from gonorrhœa, he should pursue the following course: If the applicant is otherwise in perfect health, if the case is uncomplicated and apparently likely to run a mild course, the examiner should, after relating briefly and exactly the true condition of things, recommend him as a first-class risk. Suppose, however, the ever-cautious medical director should see fit to postpone issuing the policy; who will be the loser, the company or the healthy young man, who can easily obtain insurance a few weeks later in any company he may desire? A case postponed, on account of gonorrhœa, is practically the same as lost to the company, for by the time the patient has recovered, and the medical director is ready to accept him, he will be safely landed in some other. In regard to women the writer says that if he should be asked to pass upon a female who had suffered within two years from suppurative inflammation of the ovaries he would feel in duty bound to reject her on account of the serious character of the affection and the great liability of there being a return of the symptoms, resulting perhaps in death from acute peritonitis, due to rupture of the abscess into the abdominal cavity.—*The Medical Examiner and Practitioner*, June, 1900.

Practice of Medicine and Surgery in the Higher Altitudes.—R. H. Reed makes Rock Springs, Wyo., sixty-two hundred and sixty feet above tide-water, the basis of his remarks upon typhoid fever, pneumonia, tuberculosis, shock, infection, anæsthetics, etc. There is no phthisis excepting that imported. Tent life in the open is advised for early cases. The Rocky Mountain air is favorable to all kinds of surgery. Infection is less prevalent than on the coast. Shock is usually slight even in grave injuries. Pneumonia rarely reaches the stage of gray hepatization, and the mortality is high. Ether seems decidedly irritating to the entire respiratory tract and more than usually exciting. Chloroform is there used by preference, and it is noted that it is attended with nearly the same amount of excitement as accompanies ether administration in the East.—*Columbus Medical Journal*, June, 1900.

Idiopathic Osteopsathyrosis.—Ludwig Lange considers as idiopathic osteopsathyrosis all instances of abnormal fragility of the bones for which no underlying cause can be found. He describes a case of unusual interest in a boy three years old, who altogether had had twenty-two fractures. The mother and father were healthy, and this was the fifth child. He began to walk at the age of eighteen months and was well up to the twenty-second month, when he broke the thigh by falling from a sofa. The question is considered in its various bearings, and it is thought that the prognosis in the case is favored by the fact that the boy begins again to walk. It is possible that under the well-known favorable influence of functional activity an improvement in the quality of the bone will take place, so that the patient may some time outgrow his very distressing affliction.—*Münchener medicinische Wochenschrift*, June 19, 1900.

Surgery among the Insane; its Difficulties, its Advantages, its Results.—Under the first head, A. T. Hobbs enumerates difficulties in diagnosis, examination, anæsthesia, preparation for operation, and after-treatment. The advantages are: (1) Little or no shock, as a rule, succeeds even a prolonged and dangerous operation, and post-operative pain is rarely complained of. (2) Except in occasional cases, the regimen laid out for them is strictly adhered to in spite of all whims and fancies. (3) Ether narcosis is very quickly recovered from in the insane. A gentle slapping of the face will quickly arouse the most profoundly anæsthetized patient, and very little nausea or vomiting occurs subsequent to the use of ether. The results of operative surgery, especially gynæcological, among the insane are twofold: Primarily, the restoration of physical health; secondarily, the improvement and recovery of the mental condition. In summing up mental results the statistics of 168 cases are given, divided into two groups: (1) 98 inflammatory, with an average ratio of recoveries of 51 per cent. and a ratio of mental improvement of 17 per cent.; (2) 70 non-inflammatory, with a recovery rate of 25.5 per cent. and an average ratio of mental improvement of 31 per cent. The number of deaths succeeding operation in the 168 cases was 4, or a little over 2 per cent.—*The Canadian Journal of Medicine and Surgery*, July, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 Fifth Avenue.

New York, July 21, 1900.

RUPTURE OF THE LIVER.

ACCUMULATING experience shows us that traumatic rupture of the liver involves a prognosis containing several elements beyond the immediate dangers of hemorrhage, and the later danger of peritonitis which until recently has almost always been put down as the cause of death in those patients who have survived the first few hours. The fact that peritonitis does not necessarily occur after laceration of hepatic tissue has perhaps not been sufficiently emphasized, though this fact may be of great importance in prognosis. In fact, mere laceration of the liver is not followed by peritonitis, even when the hemorrhage is inconsiderable enough to postpone death for several days, and it is only when the large or main gall ducts are torn that the infecting medium is present and finds a favorable field in blood clots and physiologically disturbed peritoneum. We are able to study the effects of intra-abdominal hemorrhage better after injuries of the liver and the anatomically similar organ, the spleen, than after lesions of any other organ, because in the case of every other organ of importance force sufficient to cause laceration will also almost certainly involve communication with some mucous tract through which the exciting cause of a complicating peritonitis will enter.

If we are confronted with a case in which the probable diagnosis of rupture of the liver is made, and in which the immediate shock is rallied from—in other words, one in which the patient does not succumb in the first few hours to shock and hemorrhage, we shall find that further developments will be along two fairly similar, though differing, lines. It is clear that, when indications are distinct enough to warrant operation, the fate of the patient is decided in a very short time; but such a state of affairs does not always exist, and we are sometimes compelled to wait and observe. One course which the case may follow is indicated by the rapid unfolding of the clinical picture of general peritonitis, too well known to need comment. A second picture is seen when peritonitis does not develop, but when there are signs of slowly or rapidly accumulating fluid in the abdominal cavity, with symptoms of loss of blood, and a temperature course which is somewhat peculiar. The peculiarity consists in a rise, with an unusual difference between the oral and rectal figures, amounting sometimes to several degrees, which is pretty certainly caused by the process of absorption of degenerating and disintegrating blood clot. The temperature usually maintains or increases its elevation until the end, and as in some other conditions may go very high.

In addition to the temperature there are other signs and symptoms in cases of this sort, which may be useful in distinguishing them from those cases with peritonitis. The distention and tenderness are both less marked than in peritonitis, and the fluid moves much more easily to different parts of the abdomen when the patient is moved. The constipation is not so obstinate as is often the case during the course of peritonitis. A case of such grave visceral injury as we are considering, in which peritonitis supervenes, is almost certainly beyond relief, but in the presence of the other condition it is possible that something in the nature of operative relief can be offered. The patient is dying from unchecked, though perhaps slow, hemorrhage, and from the entrance into his circulation of the products of disintegrating extravasated blood, or, more exactly, of the chemical substances of which the important parts of blood are formed. He may die of hemorrhage before his peritoneum has time to absorb much harmful material, but when the bleeding is active the indications for intervention are usually distinct enough to prevent delay. Should the patient, however, survive the shock and immediate effects of the hemorrhage, he still has a very serious condition with which to contend. He is weakened by loss of blood and disturbed digestion, and his peritoneum is transferring from its surface into his circulation quantities, perhaps overwhelming, of the chemical and physical break-up of blood.

We know that the peritoneum can absorb considerable quantities of blood without trouble, but beyond a certain point it seems to lose this power entirely. The patient's chance of survival under these circumstances, if treated on the expectant plan, is very small; we must, therefore, resort to something more positive in therapeutics than treating symptoms. We must get rid of the accumulated blood clots and fluid blood, and control any hemorrhage which may still be going on, though the amount of operative work must be as limited as possible. The operation thus has a double object—to clear away the blood and to explore as thoroughly as possible, so that the extent of the laceration of the liver may be known. Hot surgical salt solution will be found to be an exceedingly useful preparation in operations of this sort, both in the abdomen and for intravenous infusion, and we are justified in hoping that this line of treatment will be successful in a good proportion of cases of rupture of the liver in which there is time for any sort of systematic effort.

TYPHOID FEVER AMONG THE BRITISH TROOPS IN SOUTH AFRICA.

ENTERIC fever, the greatest scourge of armies in the field, is raging on an extensive scale in South Africa. Probably, too, its scope is wider than is publicly reported, as the war authorities for reasons

of expediency will doubtless be averse to making all the facts known, and will use their own judgment as to how much of the truth shall be suppressed. The reports, however, that have come to hand from various sources show that the situation is serious. Mr. Fripp states in a letter to the *British Medical Journal* that at the time of writing there were nearly two thousand cases of typhoid fever in Bloemfontein alone. In Kimberley, Mafeking, and Ladysmith the disease during the sieges of those towns was rife, especially in the last-named place. This condition of affairs was for obvious reasons more or less unavoidable, but it was hoped that when the opportunities arrived, by changing the location of the camps frequently and by using every possible sanitary precaution a widespread outbreak might be avoided. These sanguine anticipations have unfortunately not been realized. *The Journal of Tropical Medicine*, June 15th, says: "We have lately counted the number of deaths in the South African army from typhoid fever in one of the official lists of deaths from disease recently issued, and we find no fewer than one hundred deaths from typhoid fever occurred between May 30th and June 6th, and of these no fewer than twenty-three occurred on June 4th. It is plain from these figures alone that the army is suffering from an epidemic of typhoid fever, and, since the deaths are not reported from one station but from many stations, that the infection is widespread."

For some time after the commencement of the South African campaign the health outlook appeared decidedly favorable, but the unexpected prolongation of the war, the long sieges of Ladysmith, Kimberley, and Mafeking, and the lengthened stay of large bodies of men in the same locality, have produced the inevitable results. One disappointing feature in connection with typhoid fever in South Africa has been the failure of inoculation as a preventive. Surgeon-General Jameson reports that the results from inoculation among British soldiers going to the front has been the reverse of encouraging, and does not warrant the belief that a means of conferring immunity against this disease has been at last discovered. He further said that he had called for a return of sickness during the siege of Ladysmith, and the result was certainly somewhat singular and rather difficult to explain away. It would appear from the figures in question that inoculation against enteric fever was unfavorable to the incidence of the disease, but rather favorable to the case mortality.

Dr. Victor Vaughan, in the oration on state medicine delivered by him at the late meeting of the American Medical Association, dealing with the prevalence of and mortality from typhoid fever in our military camps in 1898, has made a valuable contribution to the literature on the subject. Among other causes he lays down the following: "Camp pollution was the greatest sanitary sin committed by the troops in 1898, inadequate space allowing a large body of men to remain on one site too long. Flies served as carriers of the disease, and infection was probably disseminated through the air in the form of dust." These last two theories are peculiarly applicable to the condition of things in South Africa, where both dust and flies at certain seasons of the year are more in evidence perhaps than in any other portion of the world.

THE TREATMENT OF GONORRHŒA.

THERE is no single remedy or procedure capable invariably of curing gonorrhœa within a certain limited time. It is pretty generally agreed that an ordinary uncomplicated attack of specific urethritis is not a dangerous disease. The conditions are, however, different at once a complication arises, and in accordance therewith gonorrhœa may become a serious or even a grave disorder with unlimited possibilities in the way of sequelæ, of which some of the best known are lymphangitis, adenitis, stricture, orchitis, epididymitis with secondary impotence, prostatitis and suppuration of the prostate gland, cystitis, pyelitis, pyonephrosis, neuralgia, rheumatic affections of the joints and the tendon-sheaths, metastases in vital organs (endocarditis), tuberculosis, especially of the genitourinary organs, neurasthenia of varying severity, and actual psychoses. While it is true that some of these complications and sequelæ, such as stricture of the urethra, may result from the long duration of the disease, and that others are unavoidable and no cause can be discovered for them, it is likewise true that some complications may be due to improper treatment, or at least their development may be favored thereby. The fundamental principle in the treatment of gonorrhœa is that the therapeutic measures employed should be so applied that complications may, so far as possible, be avoided.

With these preliminary considerations Casper (*Berliner klinische Wochenschrift*, No. 22, 1900) advises against all abortive treatment as not accomplishing the desired object, but favoring the occurrence of complications. The symptoms of the disease do not appear until some days after the gonococci have penetrated the mucous membrane of the urethra. The introduction of instruments into the urethra during the acute stage, so long as a florid, purulent discharge is still taking place, is contraindicated, as are also injections that induce irritation of the urethra or aggravate existing inflammation. Some cases of acute gonorrhœa set in with marked inflammatory manifestations, while others are wholly unattended therewith. The latter occur especially in patients who have previously had gonorrhœa. In both groups injections may be begun on the first day, but in the first no remedy should be employed that causes irritation or aggravates the inflammatory process, such as preparations of silver. Under these circumstances potassium permanganate may be employed in dilutions of from 1:10,000 to 1:8,000. In the less acute stage injections of antiseptic silver salts are useful, and of these the nitrate is the best. This may be employed first in a concentration of 1:10,000, gradually increased to a strength of 1:4,000. Both of these are irritating and should therefore never be employed alone, but always in association with

astringent, secretion-reducing, and antiphlogistic agents. Thus, a combination of silver nitrate with potassium permanganate is injected first; then silver nitrate and zinc sulphate are subsequently employed; and finally potassium permanganate and zinc sulphate in the last stage. The more frequently the injections are made the better. Attempts have been made to destroy the gonococci and control the secretion by means of a single preparation—zinc permanganate—but this has not proved so successful as the combination of zinc sulphate with potassium permanganate.

Similar principles govern the treatment of acute gonorrhœal cystitis. In a large number of such cases improvement and recovery can be brought about by means of diet, rest, diuretics, and balsamics. Should these fail and the second portion of urine voided remain turbid, resort may be had to irrigation through a catheter of the posterior urethra with solutions of silver, but this should not be begun too early. In cases of chronic gonorrhœa in which the injections, usually made by the patient, do not reach the affected parts, namely, the posterior urethra and the more superficial layers of the submucosa, relief can be afforded with certainty and promptitude by means of instillations according to the method of Guyon, or irrigation with potassium permanganate according to the method of Janet, or a combination of both.

Two varieties of chronic gonorrhœa occur that do not respond even to local measures, namely, one that resists treatment of all kinds, and another that yields only so long as the treatment is maintained, but recurs as soon as this is suspended. The first is almost always glandular and infiltrating, and the other is attended with the presence of inflammatory processes in adjacent glands, especially the prostate. The former is rather uncommon and the treatment should be jointly mechanical and chemical. Bougies may be used, dilatation of the urethra may be carefully and judiciously practised, local urethrotomy may possibly be undertaken, and injections and irrigations should be employed in the intervals.

The proportion of cases of chronic urethritis complicated by prostatitis is quite large. The diagnosis must be based upon the discovery on microscopic examination of leucocytes in the fluid expressed from the prostate gland through the rectum. The results of treatment in these cases are not very gratifying. The composition of the prostatic secretion is uninfluenced by the use of iodine or ichthyol or electricity, or of injections of hot water, although the subjective symptoms may be relieved by the last. Cauterization has been proposed in the treatment of prostatitis, but the results cannot yet be definitely estimated. The only certain and harmless means of influencing favorably the morbid process consists in systematic massage and expression of the gland. This should be done three times a week for months by a masseur, while urethral injections are made or irrigation is practised. Should these fail the treatment selected will depend upon whether the process is still infectious or not; namely, whether gonococci are present in the discharge or not. In the former event the treatment by well-known methods should be persisted in until the cocci have disappeared. In the other cases no further treatment may be required at all.

News of the Week.

Dr. F. Savary Pearce has been elected clinical professor of diseases of the nervous system in the Medico-Chirurgical College of Philadelphia, succeeding Dr. C. W. Burr, resigned.

St. Vincent's Foundling Asylum, Montclair.—The Sisters of Charity have opened a new institution for homeless infants at 45 Elm Street, Montclair, N. J. It is known as St. Vincent's Foundling Asylum. It is non-sectarian, and the present accommodations provide for one hundred infants. The medical staff consists of Drs. J. S. Brown and M. J. Synnott, of Montclair.

The Rocky Mountain Interstate Medical Association.—The second annual meeting of this society will be held in Butte, August 28th and 29th. The officers of this association are: *President*, Dr. C. K. Cole, of Helena; *First Vice-President*, Dr. Leonard Freeman, of Denver; *Second Vice-President*, Dr. R. Harvey Reed, of Rock Springs; *Treasurer*, Dr. Charles G. Plummer, of Salt Lake City; *Recording Secretary*, Dr. Donald Campbell, of Butte; *Corresponding Secretary*, Dr. S. D. Hopkins, of Denver, Colo.

High Death Rate in Philadelphia.—The effects of the summer's intense heat are still visible in the mortality records. There were reported to the Philadelphia bureau of health 633 deaths for the week ended July 14th, being 89 more than for the preceding week, and 151 more than for the corresponding week of the previous year. Among the more important causes of death were: cholera infantum 96 cases, pulmonary tuberculosis 65, marasmus 38, sunstroke 33, heart disease 31, inflammation of the stomach and bowels 24, pneumonia 26, apoplexy 21, nephritis 20, convulsions 19, inanition 18, uræmia 18, diphtheria 17, inflammation of the brain 13, typhoid fever 11, paralysis 11, old age 10.

Reorganization of the Red Cross.—On July 10th the American National Red Cross surrendered its charter of incorporation under the law of the District of Columbia and reorganized under the national charter granted by special act of Congress at the last session. More than a majority of the fifty-five incorporators named by the act were either present or represented at the meeting on that day in Washington. A constitution and by-laws were adopted, and Miss Clara Barton, B. H. Warner, Stephen E. Barton, Miss Ellen Spencer Mussey, William Flather, Mrs. James Tanner, and H. B. F. Macfarland, of the District of Columbia; Walter P. Phillips, of Connecticut; W. H. Michael, of Nebraska; Samuel E. Jarvis, of New York; A. C. Kaufman, of South Carolina; Joseph Gardner,

of Indiana; Gen. Daniel Hastings, of Pennsylvania, and Mrs. Phebe Hearst, of California, were elected members of the board of control, which will choose officers.

Dr. H. W. Lincoln has been appointed gastrologist to the Bushwick Central Hospital, Brooklyn.

The Yellow-Fever Outbreak at Quemados is at an end, no cases having been reported from there this month.

The Plague continues at Hong Kong, the report for the first week in July showing sixty-eight new cases and sixty-five deaths.

Dr. Marie L. Benoit, of this city, has been appointed woman physician to the State Custodial Asylum for Women at Newark, N. Y.

Noisy Chicago.—The mayor of Chicago has vetoed the anti-noise ordinance passed by the city fathers, and advises a removal to Philadelphia for those who object to the roar and racket of a live city.

The Brooklyn Water Supply.—According to newspaper reports, there are several cases of typhoid fever along the Massapequa section of the watershed from which the supply for Brooklyn is obtained.

Formaldehyde in Milk.—Many milk dealers in New Jersey have been arrested on the complaint of the State dairy commissioner for adulterating milk, the special adulterant being formaldehyde, added as a preservative.

Morton County, Kansas, which has a population of about four hundred, is peculiar. There has been no case of serious illness and no physician in the county for over a year. Which is cause and which is effect is now under discussion by the professional jokers.

Another Medical Governor in Maine.—The Republican nominee for governor of Maine is Dr. John F. Hill, of Augusta. He is a graduate of the Bowdoin Medical College in 1877 and of the Long Island College Hospital in 1887, but has large business interests outside of medicine.

Dr. Thomas M. Lippitt, the surgeon in charge of the marines sent as a legation guard to Peking, was an assistant surgeon in the army. He was born in Berryville, Va., in 1873, was graduated from the Starling Medical College in 1897, and was commissioned assistant surgeon in the navy June 27, 1898. During the Spanish war he served on the hospital ship *Solace*, and after the war was attached to the flagship *Baltimore* on the Asiatic station. Since then he had served on the *Oregon* and the *Newark*, going to Taku with the marine detachment aboard the latter vessel.

Texas Threatened with Yellow Fever.—Numerous Italians employed in building the Vera Cruz and Pacific Railroad in Mexico have deserted their work because of an outbreak of yellow fever among them. They are wandering in bands through Mexico, Texas being their objective point. Coming as they do direct from infected camps, it is feared that they will spread the disease throughout their route of travel in Mexico and Texas. Despite the fact that a close watch is being kept to prevent their crossing the Rio Grande, a large number have succeeded in evading the quarantine inspectors and customs officials, and are now scattered throughout Texas.

Ethnology at the Pan-American Exposition.—The department of ethnology and archæology of the Pan-American Exposition has been placed in charge of Dr. A. L. Benedict, of Buffalo, who requests information and the loan of collections for the use of this department.

Famine and Disease in India.—According to a report of the governor of Bombay, there were 9,928 cases of cholera in the famine districts during the week ending July 7, of which 6,474 were fatal, and in the native states there were 9,526 cases, of which 5,892 were fatal. There have been heavy rains lately, and the sowing of grain has begun; but, notwithstanding the improved prospects, no diminution of relief will be possible for a long time.

A Hospital for Tropical Diseases in England.—It is stated in *The Hospital* that a memorial hospital for tropical diseases is to be founded in honor of the late Miss Mary Kingsley, and to be called after her name. Mr. A. L. Jones, the chairman of the Liverpool School for Tropical Diseases, has headed a subscription list with £1,000; Mr. Blaize, of Lagos, has given £500, and other promises have been made.

Diphtheria in a Faith-Cure Colony.—Twenty-five children, inmates of the "Zook Zion," in Whiteside County, Illinois, have been ill with diphtheria, or have died of the disease during the past week. The adult members of the colony refused all medical attendance for the sick children, and so the health authorities quarantined the place, and the inmates died or recovered according to their varying powers of resistance.

The Medical Directory of the City of New York for 1900 has just been issued. The directory is published by the Medical Society of the County of New York, and contains information chiefly concerning the members of that society and of the Medical Society of the County of Kings, but the membership in city societies and hospital appointments in New York hospitals only are given. There are also lists giving residence, office hours, and place and date of graduation of all legally qualified practitioners in New York City. The names of physicians practising in New York, New Jersey, and Connecticut are also given, but they are, as a rule, unaccompanied by any data other than indication as to the school of practice followed.

The Study of Physiognomy is not always a safe pursuit, as a Bulgarian journalist named Sangoff has learned to his cost. He wrote an article not long ago in a Sofia paper on the subject of the relation of the nose to character. After discussing the various shapes, he came to the conclusion that persons with long noses are often bad characters. The public prosecutor regarded this as a case of *lèse majesté*, be-

cause Prince Ferdinand has a long nose. Sangoff was arrested, tried, and sentenced to three days' imprisonment.

Diseases at Tien-Tsin.—Among the lesser evils afflicting the inhabitants of Tien-Tsin are scarlet fever and plague, epidemics of which are reported to be raging there, the former among the whites, the latter among the natives. Plague is said also to have been prevalent in Peking for some time. The only Europeans attacked have been four Italian priests, who lived among the natives and who died early in June.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending July 14, 1900. July 6th.—Passed Assistant Surgeon F. W. Olcott detached from the recruiting rendezvous, Philadelphia, Pa., and ordered home and granted sick leave for two months. Passed Assistant Surgeon W. B. Grove detached from the *Scindia* and ordered home. July 9th.—Surgeon W. H. Rush granted sick leave until October 1st.

The Sanitary Condition at Cape Nome.—General Randal, at Fort St. Michael, Alaska, reports that the health condition at Cape Nome is serious, measles, typhoid fever, and smallpox being in the camp. There were eighteen cases of the latter disease reported on July 1st, and the disease was spreading. The chief surgeon of the department was placed in charge of sanitary matters there, with instructions to employ three acting assistant surgeons to aid him. Regulations for better sanitation of the place were issued and every effort will be made to improve the condition of affairs and control the spread of the disease. The epidemic is said to have started from two cases of smallpox brought on a steamer from the south. The ship's officers were afraid they would not be permitted to land their passengers, so hurriedly disembarked them at night, and the infection was thus spread in all directions through the camp.

Leprosy in Crete.—We learn from the *British Medical Journal* that Drs. O. Cahnheim, of Dresden, and Ehlers, of Copenhagen, have completed the investigation on leprosy in the island of Crete, which they undertook at the instance of Prince George of Greece, the high commissioner of the island. In the provisional report which they have presented to the prince, they state that they found 380 lepers, of whom they personally examined 293. Of these, 153 (92 men, 61 women) were of the tubercular, and 170 (79 men, 91 women) of the anæsthetic form. As in cold countries the proportion of tubercular to anæsthetic cases is as 1 to 2, and in hotter climates as 1 to 3, the figures quoted appear to warrant the assumption that the total number of lepers in Crete is from 600 to 800. The investigators have no doubt that Zambaco Pasha's estimate of 4,000 is immensely exaggerated. Drs. Cahnheim and Ehlers were able to satisfy themselves that the disease was on the increase in Crete. The type of the disease met with in Crete is less severe than in colder regions, and the tendency to cure is on the whole greater. Prince George of Greece is anxious that the isolation of lepers, which is still carried out on the lines laid down by the Turks, and is therefore very defective, should be made more stringent throughout the island. It is proposed to establish an asylum for lepers, and for that purpose the peninsula of Spina Longa is considered suitable. The prince has also asked Drs. Cahnheim and Ehlers to draft a law for the repression of leprosy in accordance with the conditions of the island of Crete.

New York State Hospital for the Care of Crippled and Deformed Children.—The following gentlemen, in addition to those already announced, have been appointed upon the consulting-board of the New York State Hospital for the Care of Crippled and Deformed Children: Drs. Samuel B. Ward and A. Vander Veer, of Albany, Jarvis S. Wight and John A. McCorkle, of Brooklyn, and Richard B. Coutant, of Tarrytown.

Dr. Senn Again Ready for War.—The Chicago *Tribune* says that Dr. Nicholas Senn, who served as a volunteer medical officer during the war with Spain, has again offered the United States government his services, this time to go to China to care for the American soldiers who may be wounded. As volunteer in the Spanish-American war Dr. Senn went to Cuba, where he was chief operating-surgeon in the field with the rank of lieutenant-colonel.

A Divine Healer Acknowledges His Guilt.—A man named Francis Truth, who was on trial in the United States circuit court in Boston for using the mails to defraud, has pleaded guilty on the seven indictments found against him. On five charges he was fined the maximum penalty, $500 each. The other two indictments were placed on file at the suggestion of the District Attorney as a matter of precaution. Should the man attempt to engage in any unlawful business these two indictments will be brought up against him and imprisonment imposed. He did his divine healing by correspondence, and is said to have made a moderate fortune from the advance fees received.

Association of Surgeons of the Confederate States.—The third annual meeting of this association was held in Louisville on May 30th and June 1st and 2d, under the presidency of Dr. Francis L. Parker, of Charleston, S. C. The following officers were elected for the next annual meeting, which will be held in Memphis, Tenn.: *President*, Dr. Preston B. Scott, Louisville, Ky.; *Vice-President*, Dr. J. M. Keller, Hot Springs, Ark.; *Secretary*, Dr. Deering J. Roberts, Nashville, Tenn.; *Treasurer*, Dr. V. G. Hitt, Atlanta, Ga.; *Chaplain*, Rev. George B. Overton, Louisville, Ky. It is desired to enroll all who are eligible to membership in the association, and therefore it is requested that all surgeons, assistant surgeons, acting assistant surgeons or contract surgeons, and hospital stewards, who served in the army or navy of the late Confederate States, will send their post-office address to Deering J. Roberts, M.D., secretary Surgeons' Association C. S. A., Nashville, Tenn.

Progress of Medical Science.

New York Medical Journal, July 14, 1900.

Primary Carcinoma of the Fallopian Tube. — Elizabeth Marcelis reports the case of a woman aged thirty-five years, who was operated upon successfully, but in whom a recurrence took place eighteen months later. At this latter time the case was regarded as inoperable and nothing was done. The case is notable from its rarity, there being but twenty similar cases on record. The histological points on which a diagnosis of primary carcinoma was made are as follows: (1) The absence of malignant growth in the uterus, as shown by microscopic examination of curettings at the time of operation. (2) The presence of an old salpingitis, together with the freedom of the inner end of the tube from malignant change. (3) An enlarged tube, the lumen of which was filled with carcinomatous masses of 2.5 cm. diameter; this change was found throughout two-thirds of the tube, and with the existence of a pelvic tumor for more than fifteen months. (4) The advanced stage of the growth within the tube and fairly healthy condition of the outer muscle layers. This, in view of the resistance of the tube to secondary invasion from the ovary, and that such, when occurring, usually involves the peritoneal surface first, the mucosa secondarily. (5) The ovary was not only small, but at the inner end free from the growth. (6) Microscopical evidences of a more rapid proliferation of the new cells in the ovary than in the tube.

"Floaters" in the Urine.—By this term W. F. Bernhart refers to the gonorrhœal threads so commonly met with. From experiments with fifty different specimens of urine, he arrives at the following conclusions: (1) The specific gravity of the urine is a prominent factor in the action of floaters. (2) The elements composing the floaters influence their action. (3) Their suspension at different depths in the urine is due to some mechanical interference. (4) Upon filtration of the urine all but the very lightest floaters, those composed of flocculent mucus, will sink to the bottom of the beaker. (5) The action of floaters does not alone depend upon their composition or the specific gravity of the urine.

Two Unique Rectal Cases.—S. G. Gant reports a case of chronic diarrhœa due to rectal ulceration cured by divulsion of the sphincter, curetting of the ulcer, and application of silver nitrate (thirty grains to the ounce). He believes that the continuing cause of diarrhœa is located in the colon and rectum with greater frequency than is generally supposed. He also reports a case of rectal stricture caused by stone in the bladder. A stone weighing four and a half ounces was removed, and the stricture broken up; ulcerated surfaces were curetted and urine was allowed to pass through the lithotomy (perineal) wound for a year. The latter finally closed of itself.

The Proper Care of the Infant's Nursing-Bottle.—T. W. Kilmer describes an apparatus devised by himself, for the perfect sterilization of the nursing-bottle combined with a sterilizer and pasteurizer for milk. The article is illustrated.

The Present State of the Galvano-Caustic Operation of Bottini for Ischuria.—By G. MacGowan.

Atrophy of the Ciliary Muscle.—By N. B. Jenkins.

The Elements of a Good Climate.—By P. Paquin.

Syphilis of the Brain.—By J. T. Eskridge.

Boston Medical and Surgical Journal, July 12, 1900.

A Review of Recent Studies in the Nature and Origin of Cancer.—J. C. Warren says there is little doubt that cancer is on the increase. He reviews the geographical distribution, showing the almost entire freedom of far north countries, including the northern coast line of Europe and Asia, Egypt, and Abyssinia, as well as the rarity of the disease in tropical climes. The increase has been marked in the past fifty years. In England and Wales during twenty years deaths from cancer more than doubled. In New York State cancer is the only disease tabulated which shows a progressive and steady increment. The greatest increase in this country is in San Francisco. Many points favor the inoculation or infective theory. The various theories of cause and mode of growth are reviewed. Cancer houses, streets, and villages are mentioned, as well as epidemic prevalence in certain regions. Recent experiments with blastomyces and other growths are referred to, and especial attention is directed to the first laboratory established for the study of cancer at Buffalo in this State. The parasitic theory seems plausible, but is "not proven."

Cysts in the Abdominal Wall Structurally Identical with Ovarian Cysts.—John Homans reports an operation for ovarian cyst weighing one hundred and two pounds. There was present at the same time a cyst in the abdominal wall of identical structure. Other cysts of like nature subsequently formed.

A Case of Mural Endocarditis.—By Harold Williams.

A Case of Cæsarean Section.—By T. Kittredge.

Journal of the American Medical Ass'n, July 14, 1900.

The Relation of Ethyl Alcohol to the Nutrition of the Animal Body.—W. S. Hall describes the nature of nutritive processes and answers the questions, What is food and what is alcohol? pointing out the relations of alcohol to nutrition, and how it influences certain phases of metabolism. The demonstrated facts we possess are set against each other in parallel columns.

ALCOHOL.	THE TRUTH ABOUT FOOD.
1. A certain quantity will produce a certain effect at first, but it requires more and more to produce the same effect when the drug is used habitually.	1. A certain quantity will produce a certain effect at first, and the same quantity will always produce the same effect in the healthy body.
2. When used habitually, it is likely to induce an uncontrollable desire for more, in ever-increasing amounts.	2. The habitual use of food never induces an uncontrollable desire for it, in ever-increasing amounts.
3. After its habitual use a sudden total abstinence is likely to cause a serious derangement of the central nervous system.	3. After its habitual use a sudden total abstinence never causes any derangement of the central nervous system.
4. Alcohol is oxidized rapidly in the body.	4. All foods are oxidized slowly in the body.
5. Alcohol, not being useful, is not stored in the body.	5. All foods, being useful, are stored in the body.
6. Alcohol is a product of decomposition of food in the presence of a scarcity of oxygen.	6. All foods are products of constructive activity of protoplasm in the presence of abundant oxygen.
7. Alcohol is an excretion and, in common with all excretions, is poisonous. It may be beneficial in certain phases of disease, but it is never beneficial to the healthy body.	7. All foods are formed by nature for nourishment and are by nature wholesome and always beneficial to the healthy body, though they may injure the body in certain phases of disease.
8. The use of alcohol, in common with narcotics in general, is followed by a reaction.	8. The use of foods is followed by no reaction.
9. The use of alcohol is followed by a decrease in the activity of the muscle-cells and the brain-cells.	9. The use of food is followed by an increased activity of the muscle-cells and brain-cells.
10. The use of alcohol is followed by a decrease in the secretion of CO_2.	10. The use of food is followed by an increase in the excretion of CO_2.
11. The use of alcohol is followed by an accumulation of fat through decreased activity.	11. The use of food may be followed by accumulation of fat, notwithstanding increased activity.
12. The use of alcohol is followed by a fall in body-temperature.	12. The use of food is followed by a rise in body-temperature.
13. The use of alcohol weakens and unsteadies the muscles.	13. The use of food strengthens and steadies the muscles.
14. The use of alcohol makes the brain less active and accurate.	14. The use of food makes the brain more active and accurate.

The Plague in San Francisco.—D. W. Montgomery relates eleven cases with autopsies and laboratory investigations. He presents arguments against the existence of plague and answers them. No diagnosis has been made on a living patient. He believes the plague enters a community slowly, as is here the case. The outlook for the future, he believes, is not bright. He expects the plague to appear with increased violence next winter. The daily press and the people are against the health board, but the work of the latter goes on with uninterrupted fidelity.

Diagnosis of Apoplexy Unaccompanied by Motor Paralysis.—William N. Bullard believes that apoplexy without motor symptoms is often overlooked by the general practitioner, and he presents cases showing how difficult is the diagnosis when it is impossible to obtain a history. An element in differentiation of the results of primary apoplexy from paralytic dementia or other cerebral affections is the presence or absence of symptoms characteristic of these affections, but not usual in the simple apoplexies.

The Specific Treatment of Croupous Pneumonia.—W. O. Bridges, in an attempt to solve the question whether in guaiacol carbonate and the salicylates we have a specific medication for croupous pneumonia, presents some cases showing how much reliance can be placed upon these drugs. He prefers guaiacol in cases past the stage of congestion, in the enfeebled, and when heart lesions are present. Strychnine obviates in part the depressant effect upon the heart, and so does alcohol.

Education and Legislative Control of Tuberculosis.—By Charles Denison.

Substitute Infant Feeding.—By H. D. Chapin.

Appendicular Fistula.—By J. B. Deaver.

The Philadelphia Medical Journal, July 14, 1900.

Dislocation of the Jaw in Epilepsy.—Charles J. Aldrich reports two cases of this unusual accident. The first was in the person of a woman aged twenty-one years, and the second in that of a man aged twenty-five years. In each case the first physician called failed to make a correct diagnosis. From our knowledge of the action of the facial muscles during an epileptic paroxysm, the author says, we would hardly expect a luxation of the jaw to occur as a complication.

A Case of Primary Adenocarcinoma of the Gall Bladder with Secondaries in Both Adrenals, Melanosis of Skin (Addison's Disease ?), Vitiligo, and Hypertrophy of the Pancreas.—By Aldred Scott Warthin.

Total Excision of the Scapula Alone, and with the Arm (Interscapulothoracic Amputation) : Partial Excision of the Scapula for Tumor.—By J. J. Buchanan

The Action of Rennin upon Milk-Digestion.—By I. H. Coriat.

A Case of Myoma of the Bladder.—By Otto G. Ramsay.

Medical News, July 14, 1900.

Some Remarks on the Artificial Feeding of Infants and the Regulation of the Milk Supply in the Country.—J. F. Bell points out the importance of proper artificial diet. Condensed milk, which is the most popular, is the most pernicious, being responsible for more malnutrition, etc., than all other articles combined. It is not a suitable substitute for mother's milk. A consideration of the proper modification of milk is given. There is something radically wrong in methods heretofore pursued. The care of cows, rules for milking, regulations assuring cleanliness, etc., are all considered with the view of producing an article which will not require sterilization. First of all a suitably educated dairyman must be secured, and all must be under health-board supervision.

Subphrenic Abscess following Appendicitis.—J. F. Baldwin gives two cases from his practice of this rare and often obscure and overlooked complication. An important point in diagnosis in many cases is that frequently a subphrenic abscess due to appendicitis contains gas as well as pus, due to perforation of some neighboring hollow viscus or more likely to gas-producing bacteria. The mortality under surgical procedure is not over fifty per cent., while in unrecognized cases recovery is to be expected in only about five per cent. of instances.

Tendon Transplantation in the Treatment of Deformities of the Hand.—By W. R. Townsend.

Petroleum in the Treatment of Phthisis.—By W. D. Robinson.

The Lancet, July 7, 1900.

Note on a New Medium for the Growth and Differentiation of the Bacillus Coli Communis and the Bacillus Typhi Abdominalis.—A. T. Macconkey says that in this medium advantage is taken of two well-known facts: (1) That the salts of bile are precipitated by acids, and (2) that bacillus coli communis produces acid in the presence of lactose while bacillus typhi abdominalis does not. The composition of the medium is sodium glycocholate, 0.5 per cent.; peptone, 1.5 per cent.; lactose, 0.3 to 0.5 per cent.; agar, 1.5 per cent.; tap-water, q.s. The lactose is added after filtration. If stab cultures be made in this medium with bacillus coli communis and bacillus typhi abdominalis and incubated at 42° C. for from twenty-four to forty-eight hours, it will be found that the tube inoculated with bacillus coli communis has become cloudy while the tube containing bacillus typhi abdominalis remains quite clear. If glucose be used instead of lactose, both tubes become cloudy, but the cloudiness due to bacillus coli communis begins from below and that due to bacillus typhi abdominalis from above. In plates made with the glucose medium incubated for forty-eight hours at 42° C., and then left for from three to four days exposed to the light at room temperature, the colonies gradually become orange colored.

Contagious Catarrh, or Roup, in Fowls, and Diphtheria in Man.—J. G. Sharp gives the following as his conclusions: (1) Roup-like diphtheria (including the somewhat indefinite term "croup") varies in its malignancy, sometimes being mild with only one or two deaths in a large hen-run, while the next epidemic may almost clear out the whole coop. (2) The disease does not appear to be transmissible to man, for those handling the affected birds without any precautions do not suffer from any disease resembling diphtheria. (3) Paralysis was, according to my observations, absent in roup cases. (4) The disease is evidently a highly contagious catarrh and may correspond to the morve or fowl glanders of the French. (5) Roup probably differs entirely from "fowl diphtheria," so called. (6) As we have already seen, bird fanciers distinguish between a "dry" roup and a "wet" roup. Dry roup is most likely a simple benign catarrh corresponding to the recurring croup affecting children, especially those inhabiting valleys and near a river bank. Wet roup, on the other hand, in its malignancy resembles diphtheria and membranous croup. (7) The micro-organism of roup (the wet variety or malignant variety) probably lives for a considerable time at least in the earth near the surface, and thus it is readily spread from animal to animal (as well as by direct contact with affected birds). (8) Conditions of soil and surroundings favorable to the spread of diphtheria would likewise appear to favor the spread of roup in fowls.

One Hundred Consecutive Cases of Abdominal Section in Hospital Practice, Without a Death.—Since W. Duncan's paper was sent in for publication he has added eight more successful cases to his list. He describes in detail his method of preparation of the patient, his routine with reference to assistants, instruments, sponges, flushing out the abdomen, drainage, and after-care. He combats shock by strychnine and endeavors to prevent tympanites by passing a soft rectal tube every four hours, and then, if flatus is not passing freely, giving an enema of an ounce of oil of turpentine in a pint of hot water. This is given high up and repeated two or three times daily until escape of flatus is free.

Unusual Complication following Gastro-Jejunostomy.—W. H. Brown's patient did well for two weeks following operation. At the end of that time, evidences of obstruction coming on, the abdomen was reopened. The junction between stomach and gut was all right, but insertion of the finger through an incision in the stomach two inches above the junction showed absence of bone-plate and no trace of an opening. A membrane had formed where the opening had originally been and was easily torn through with the finger. From this time on, recovery was uneventful.

On the Treatment of So-Called "Hay Fever" or Summer Catarrh.—Karl Grube has found in all of his cases a gouty tendency, and therefore lays great stress on a careful and strict regulation of the diet. His local treatment consists in the application of the Neuenahr waters in the form of inhalations, gargle, and nose-douche. Hot baths and massage may be added when there are, in addition to catarrhal symptoms, muscular and articular pains. He admits that cases without a distinct gouty history are not benefited by this treatment.

Hydatid Cyst in a Native of India.—This case is reported by W. J. Buchanan, as cysts of this nature are very rarely found in natives of India who have never left their homes.

Münchener medicinische Wochenschrift, June 26, 1900.

A Contribution to the Study of Multiple Neuritis.—Henrici discusses the etiology of this disease, and inclines to the views of Strümpell, who believes it to be always ultimately referable to the action of some poison, organic or inorganic. The neuritis following the infectious diseases is of the former, while that due to lead, arsenic, or alcohol is of the latter variety. These toxic substances, whether of external or internal origin, affect the peripheral nerve fibres most strongly, the cellular elements and the fibres situated in the central nervous system being more resistant. The author illustrates his statements with detailed accounts of five cases, one an arsenical neuritis, one following pneumonia, and the other three occurring in alcoholics. Alcohol is to be considered as merely a predisposing agent; there is nearly always to be found in addition tuberculosis, diabetes, or some febrile disease which forms the determining factor in the etiology.

Perithelioma of the Carotid Gland.—Heimleth relates the difficulties experienced in diagnosing and removing a

tumor which finally turned out to be a perithelioma of the carotid gland. Only six similar cases are to be found in the literature, and these are given in brief by the author. Nothing definite is known of the causation of these growths, which occur at all ages and give all the manifestations of malignancy. The frequency with which they have shown themselves at about the end of puberty gives color to the belief that the increased general hyperplastic activity of this period does not receive its natural check, and that in consequence of mechanical or inflammatory stimuli the overgrowth is excited.

The Agglutinating Properties of the Blood of a Healthy Infant Born of a Typhoid Mother.—Zängerle reports the case of a woman who in the third week of her typhoid gave birth to a child which continued perfectly well until three months later, when it died of a combination of varicella and pneumonia. The autopsy showed the absence of any of the lesions likely to have been caused by an intrauterine infection of the fœtus by typhoid, yet on the second day after birth the child's blood gave a definite Widal reaction in a dilution of 1 : 30 of the blood, corresponding to 1 : 60 of the serum. While the observation has been made often enough that intrauterine infection with typhoid is possible, the number of instances reported in which a healthy child was born of a woman sick of the disease, and then gave the characteristic serum reaction, is limited to five, which are abstracted by the author.

The Danger of Tubercle Infection through Milk and Dairy Products.—Lydia Rabinowitsch recapitulates the dangers to the community at large that exist in the constantly increasing number of tuberculous cattle used for the production of milk and its various modifications exposed for sale. Although for obvious reasons the general legally enforced application of the tuberculin reaction is meeting with much opposition at the hands of dairymen, it still represents the best and most reliable test, and it is only by its rigid employment that an absolutely tubercle-free milk supply can be obtained. This is conclusively shown by the author's investigation of the product of eight Berlin dairies supplying at an increased price what is ostensibly a germ-free milk to be used for children and invalids. In three of these establishments the tuberculin test is regularly applied and the milk furnished was found uncontaminated by the bacilli. In the other five dairies clinical observation is depended on to detect disease in the cattle; repeated examination demonstrated the presence of active virulent tubercle bacilli in the milk of three of these. The author's investigations were carried on to a study of various other dairy products. "Plasmon" (Siebold's milk albumen) was found free from pollution, but pot-cheese and kefir both furnished virulent cultures. Margarin and its modification "sana" being prepared from beef suet, and containing no milk, are supposably free from danger of infection, but the author calls attention to the fact that the fat used in their manufacture may easily contain diseased lymph glands, and as a matter of fact the two samples examined were found to give a positive result bacteriologically.

Fat Embolism.—Ribbert gainsays the prevalent theory as to the mechanics of fat embolism, and believes that the following considerations prove the fallacy of the belief that the oil globules found in the pulmonary and systemic capillaries are thrown into the circulation through the local laceration of bone marrow at the site of fracture. In the first place the torn vessels are themselves bleeding, *i.e.*, pouring out their contents, and therefore incapable of receiving and carrying off anything, and though it may be said that the local pressure is greater than that of the capillaries, still this same pressure is also acting by compressing and obstructing the orifices of the ruptured vessels. Secondly, the amount of fat thus set free is never sufficient to produce the degree of embolism found. In the third place, very pronounced fat embolism often follows comparatively insignificant fractures, and is nearly always present in fracture of the skull when only non-fatty bones are injured. The results of his clinical observations and animal experimentation incline the author to believe that the jarring and commotion produced in the bone marrow at large throughout the body by every serious traumatism cause the fat to enter the circulation, and he maintains that every shock, such even as that experienced in jumping from a height, is sufficient to produce a greater or less degree of fat embolism.

A New Club-Shaped Pathogenic Bacterium Found in Lymph (Corynebacterium Lymphæ Vaccinalis).—Levy and Fickler publish a preliminary report on a bacterium isolated by them from calves' vaccine lymph. Two varieties were cultivated, possessing practically the same characteristics but differing in that, when grown on Loeffler's blood serum, the one produces an orange-yellow coloring-matter, while cultures of the other are colorless. Young cultures consist of small wedge-shaped forms or cylinders of medium size; as they grow older the cylinders exhibit a tendency to the production of club-shaped forms which are slightly curved and beaded. The aniline colors are readily taken up, Gram's stain is positive, but in spite of their evident relationship to the diphtheria bacillus Neisser's stain for the metachromatic bodies is negative. Nakanishi has just published (*Centralbl. f. Bact. Parasit. u. Infect.*, vol. xxvii., Nos. 18 and 19) an account of a bacillus found by him constantly in the vaccine pustules of children and calves, and the authors consider their bacillus as very similar to, if not identical with this, though they think it too soon to indorse his belief that this is the specific organism of vaccinia and variola.

A Rare Complication in Tracheotomy.—Thomas, in operating on a two-year-old child, whose larynx was filled with diphtheritic membrane, had the unusual and disconcerting experience of being unable to find any trachea. Having explored the middle line of the neck in vain, two fibrous cords were exposed on either side, but an attempt to open each of these under the impression that it might be the very much altered trachea was unsuccessful. Further dissection revealed the larynx crowded close down on the jugular notch of the sternum. The thyroid cartilages were split and an endeavor was made to pass a tube in this way, but the manœuvre did not succeed, and the patient died in a very few moments. At the autopsy it was found that the fibrous cords were the greatly contracted and degenerated sternohyoid muscles, which had pulled the larynx down to the sternum, and on cutting these the trachea popped into view. No explanation of the anomaly could be given.

Investigation of the Behavior of Milk Bacteria in the Milk Thermophor.—By Dunbar and Dreyer.

Contributions to the Significance of the Oliver-Cardarelli Symptom.—By Ritook.

Iodipin.—By Klingmüller.

Berliner klinische Wochenschrift, June 25, 1900.

Prognosis of Glycosuria and Diabetes.—F. Hirschfeld finds in the literature of recent times a hopeful view as to the prognosis of the milder forms ot the disease. According to his own researches, a relative cure is to be looked for (that is, a freedom from sugar with the ingestion of 200 gm. of carbohydrates daily) if upon the outbreak of the affection eighty to eighty-five per cent. of the carbohydrates is burned up in the system. The assimilative power, with reference to this form of ingesta, he has seen diminished after influenza, certain forms of colic, and in an especially marked degree after gangrene and furunculosis. A deterioration with reference to glycosuria is seen through an increase and an improvement through a decrease in the quantity of the urine. Sometimes accompanying a rapid increase of weight an increase in glycosuria is seen, but it will subside under a restricted diet. The heart weakness occurring in diabetes is favorably influenced by a diet of diminished carbohydrates, but these should not be wholly given up.

A Case of Complete Transposition of the Viscera Associated with Dissecting Aneurism of the Aorta.—A. Barbo describes the case, which was that of a woman aged seventy-four years, who died of senile dementia. Autopsy revealed complete transposition of the viscera. A most careful description is given of the arrangement of the various organs. The aorta arose from the right ventricle and the pulmonary artery from the left. The aneurism was situated in that part of the aorta within the pericardial sac into which it had ruptured. The adventitia had been separated from the median coat. A valuable bibliography of the literature of dissecting aneurisms is given.

The Present Condition of Our Knowledge of the Anatomical Relations of the Cerebellum to the Remainder of the Nervous System, and its Significance for the Appreciation of the Symptomatology and Diagnosis of Cerebellar Diseases.—By L. Bruns.

The Anatomy of the Brain and Psychology.—By L. Edinger.

French Journals.

The Treatment of Wens by Interstitial Injection of Ether.—E. Sergent presents a new method of treating sebaceous cysts by injecting pure sulphuric ether by means of a sterile syringe whose platinum needle has been passed through the flame. No cyst which has begun to show signs of in-

flammation should be so treated. The surface should be prepared as for any operation. Cysts upon the face, when small, require only five or six drops of ether at a time, but the needle can be left in place, the syringe unscrewed, and subsequent injections be made at the same sitting. Each day or two the needle is introduced by the same opening (a follicular orifice). Ten or twelve sittings may be required before proceeding to the extraction of the sac. An eschar of pin-head size at the point of injection, together with flaccidity of the tumor, indicates the time for extracting the sac. The advantages of the method are bloodless removal without pain or subsequent scarring.—*La Presse Médicale*, June 30, 1900.

The Slow Pulse in Syphilis.—M. Degny says that syphilis affects the heart not only by way of its muscular fibres, its interstitial tissues, and its vessels, but also by central innervation giving a permanently slow pulse. The history of one case is given and several others are referred to. The Stokes-Adams syndrome can be brought about in three different ways: by the production of bulbo-cerebral or bulbo-protuberant gummous tumors; by the production of arteriosclerosis or of arterial lesions situated wholly or predominately in the bulb (as is the case in the majority of instances); or, as Thornton has observed, by syphilitic products compressing the pneumogastric at some point in its course.—*Journal des Praticiens*, June 30, 1900.

Treatment of Syphilis by Inunctions with Calomel Ointment.—J. Kazandjieff recommends in place of mercurial ointment frictions with calomel pomade. Each dose contains 4 gm. of calomel, two each of vaseline and lard, and 80 cgm. of essence of turpentine. It is more cleanly, and does not irritate the skin. It is applied to the back and lower extremities, by choice, each morning, and a bath is given three times per week.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, July 1, 1900.

Zeitschrift f. klinische Medicin, vol. xl., Nos. 3 and 4, 1900.

Artificial Modification of the Gastric Secretion.—According to Alder, bismuth subnitrate is so far the only drug that experience has shown to possess a definite therapeutic value in causing a diminished secretion of hydrochloric acid in cases of hyperchlorhydria. Actuated by the results of Riegel, obtained by experiments on animals, he was impelled to study the effect of atropine on the gastric secretion, the theory being that as the vagus is the agent primarily concerned in controlling this function and atropine inhibits the action of the nerve, the administration of the drug ought to decrease the amount of gastric juice formed. This was found to be true in practice and by analysis of test meals given first without and then with atropine; it was observed that under the latter condition the percentage of hydrochloric acid was very markedly cut down. The same result is produced by the administration of considerable quantities of sugar solution, and both of these substances are recommended as being of value in the treatment of cases of hyperacidity.

The Clinical Aspects of Abscess of the Lung.—Jacobson states that the prognosis in abscess of the lung depends largely on the nature of the perforation through which the pus finds its way into the bronchus, to be expectorated. A large opening corresponds to free drainage and an acute course, while in cases in which the orifice is small the discharge takes place slowly and the course accordingly becomes chronic and the outlook more unfavorable. Serous or purulent exudation into the pleura does not necessarily increase the gravity of the situation, but metastatic abscesses, especially in the brain, are always serious complications. Under the treatment pneumonotomy is to be considered as adapted particularly to the acute cases, and gives its best results when the collection of pus is subpleural or at least not very deeply situated.

The Interrelationship of Diabetes Mellitus, Abdominal Colic, and Œdema.—Ebstein discusses this symptom syndrome, taking as text a case history in which frequent severe attacks of abdominal colic were accompanied by a glycosuria which at first was evanescent but later became permanent, and in which finally well-marked œdema of the feet, legs, and genitals set in. The possibility is noted of impacted gall stones or pancreatic concretions producing both the attacks of pain and at the same time through direct or indirect action on the pancreas determining a state of glycosuria. In explaining the œdema, inasmuch as all the usual local and general causes could be excluded, the theory is advanced that the effect on the vasomotor nerves of the toxic substances present may be sufficient to produce, or at least predispose to, a widespread œdema.

Fat Diet in Hyperacidity.—Backman draws the following conclusions from an elaborate series of test-meal experiments with different foods in cases of hyperacidity: (1) Fat (butter or cream) usually markedly decreases the free hydrochloric acid in hyperacidity. (2) Fat probably exerts an inhibitory action on the total hydrochloric-acid secretion. (3) Butter and cream do not prolong gastric digestion. (4) The presence of fat does not retard the digestion of carbohydrates nor inhibit the secretion of pepsin. (5) Fat, especially in the form of butter and cream, is an eminently suitable food-stuff in cases of hyperacidity.

The Percussion of the Spleen-Lung Boundary.—Buttersack says that under the conditions usually present, viz., with the lungs in the mid-respiratory phase, percussion of the limit between spleen and lung is very difficult. If, however, the patient takes a deep breath, the contrast between the hyper-resonant pulmonary tissue and the spleen dulness is very pronounced, while forced expiration is also more favorable, for then the organ is forced more closely against the abdominal wall and its outlines are very distinctly appreciable.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL SUNDAY FUND—PRINCE OF WALES' FUND AND MEDICAL SCHOOLS—THE ARMY MEDICAL SERVICE—ALLEGED WAR HOSPITAL DEFICIENCIES—EXIT MIDWIVES BILL—CAMBRIDGE SUMMER SCHOOL—SIR WILLIAM GAIRDNER.

London, June 29, 1900.

Chilly, gloomy, cold, unseasonable, such were the milder adjectives applied to the weather on Sunday. And it was Hospital Sunday. The sermons were forthcoming in most of the churches and chapels, but the congregations were too often scanty, and fears were freely expressed for the fund. The lord mayor, undeterred by the other demands on the public benevolence, had issued an open letter asking that last year's amount might be more than doubled—asking, in fact, for £100,000. It is hardly to be expected he will get it, and if last year's collection be equalled it will be as much as I anticipate. On Monday evening £16,000 had reached the Mansion House.

A memorial was sent to the Prince of Wales three months ago from the council of the Metropolitan Radical Federation purporting to represent the Radical clubs. This Council had the assurance to pretend that the Prince's hospital committee had disregarded His Royal Highness' intentions and devoted part of the funds to medical schools and laboratories. You may judge the tone of the memorial from the fact that it incorporated an article in *The Contemporary Review* by Mr. Stephen Coleridge, to whose allegations about vivisection I have previously referred. The executive committee of the Prince's hospital fund have issued a report which completely disproves the "scandalous charge," in which they state that the honorary secretary of the Federation has already been informed that no grant had been made toward the support of laboratories. They go on to deny in detail the statements in the memorial and to explain some of the figures which had been impugned. Mr. Coleridge and his followers have thus obtained an advertisement which the article in *The Contemporary* could not give, but it may be questioned whether they will feel much satisfaction in the result, which is calculated to enlighten the public on the value of assertions made by Mr. Coleridge or the Radical Federation he has thus led by the nose. One can feel pity for the ignorance of the person who can believe that hospital patients are only material for experiments and vivisection by doctors. For an educated barrister, even though the advocate of the antivivisectionists, contempt seems more appropriate.

The Royal Army Medical Corps has had so much praise that it was sure to be assailed by some one. A fine encomium was passed upon the corps on the 18th inst. by Sir W. MacCormac on the occasion of his receiving the

freedom of the Salters' Company. He said he had seen all the organizations for the relief of the sick and wounded and could "speak in their praise without stint; the provision made for them has been unexampled in the history of war and profuse in every way." Other commendation followed, and the newspapers generally praised the Royal Army Medical Corps as the brightest spot in the army—until Wednesday last, when *The Times* published a letter from Mr. Burdett-Coutts, M.P., giving a sensational description of the sufferings and hardships to which our wounded soldiers are subject. He has just returned from South Africa, and declares he is impelled to speak out by the knowledge that distinguished medical men who have come home have testified to the perfection of the arrangements. In three columns of *The Times* Mr. Burdett-Coutts piles up the horrors endured by the wounded and typhoid patients—most of which, to those with experience, are clearly of the unavoidable kind. The challenge thrown down thus to the medical men was promptly taken up by Mr. Treves, who states his own experience, repeats his previous assertions, and says he cannot believe "our sick have been treated with neglect and inhumanity, as Mr. Burdett-Coutts asserts." You will not be surprised from this to learn that the subject has almost displaced every other from conversation among doctors, and that the newspapers are coming out with large head-lines on "War Hospital Horrors" and "War Hospital Scandal." Parliament was moved from the apathy into which it had fallen and demanded explanations of ministers. Mr. Balfour accordingly read extracts from a despatch of Lord Roberts, who tells how distressed he was that his men had to suffer much, and explains the impossibility of avoiding terrible scenes after a long march, repeated fights, and interruption to the long line of railway. He had himself constantly visited the hospitals, and considers that after a very short time they were in good order and not overcrowded. Lord Roberts says he "has no wish to shirk responsibility or to screen any shortcomings which may be proved against the Royal Army Medical Corps," and he suggests that a "committee, say of two medical men of recognized ability, and some man of sound common-sense, should proceed to South Africa in order to furnish a full report on the working of the medical arrangements throughout the war." As Mr. Balfour read the reference to "some man of common-sense," the house indulged in roars of laughter and cheers—a testimonial which Mr. Burdett-Coutts perhaps did not anticipate when he penned his sensational charges. Nobody supposes Lord Roberts intended the phrase to convey the meaning which honorable members seemed to see in it, but the House was intensely amused.

Sir Evelyn Wood was at a dinner of the civil engineers on Wednesday evening, and declared that the sick and wounded had been adequately looked after—and he ought to know. Lord Wantage, V.C., is chairman of the Red Cross Society, and its committee meets twice a week to receive and consider reports from the field, but no such complaints have reached them. He says Mr. Coutts attended a meeting before he went and offered to act as their commissioner, but as he was making only a flying visit the offer was not accepted. He did not inform the committee of what he now complains, or they would have remedied what needed reform. This shows how a person without proper information may take a roving commission and perhaps fall into errors as to what he sees. Mr. Coutts is evidently not qualified to write about war or to judge what is preventable. He may have "sound common-sense," but I never heard of his doing anything to show it.

Mr. Julian Ralph is a correspondent of far superior intelligence. He was out for *The Daily Mail*, and sent home interesting descriptions—but not a word about this matter, until now on his return he proceeds to father Mr. Coutts' statements, though he says he can tell only of "chance observations and impressions"—a very loose way of offering evidence. Then he repeats what he heard from an officer, that at one hospital they were "trying on famished patients a new German method of treatment rightly called 'the starvation treatment.'" Then he says he knows no more of the skill required that is to be seen in this "criminal adoption of the starvation method at Bloemfontein." He then goes on to declare that one of the greatest English surgeons told him the average army surgeon was a mere tyro, because the War Office would not let them go to Paris, Berlin, or New York in their holidays (?) and only those stationed near London "had a chance to walk the metropolitan hospitals"! Evidently Mr. Ralph has mixed up a statement of one of the army grievances about "study furlough," and made a mess of it all. He is a shrewd and able correspondent, and he acknowledges he made no notes on this matter and did not study it. I can therefore hardly excuse him for winding up his inconsequent statements by calling the treatment of the sick and wounded "primitive, cruel, and almost barbaric, as well as needless and inexcusable."

Really an experienced war correspondent should be more reticent with condemnatory adjectives. Some army surgeon may be retorting that these of his choice are more applicable to the man who accuses the staff on the strength of "chance impressions."

There is to be a debate on the subject in the House of Commons this evening.

Exit the midwives bill—it has gone out as in a farce. It came on, was opposed for a time, and to save it from the fate of rejection one of its supporters talked it out. Well, we are rid of it for another year, but shall no doubt then have to fight it again.

The Cambridge Summer School for Practitioners is to be discontinued, as the response has been too small to the offer made. But the Pathological Society will meet at Cambridge on the 30th, and there wind up its session, having been invited to do so by Professor Dr. Sims Woodhead.

Sir William Gairdner was last week entertained to a farewell dinner at which a number of distinguished persons were present. In his speech replying to the toast of his health he said he had lived thirty-eight years of life preprofessorially and thirty-eight professorially, and that he had had to ask for only two things that were of much account—his professorship and his wife. The rest came unasked, and he believed many went about suffering much because they were always running to and fro begging for all manner of things and grudging others their success. He was inclined, like Lord Kelvin, to regard his career as failing from poverty of accomplishment compared with the ideal he had set himself.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE NEW PASTEUR HOSPITAL—THE BAZY-ALBARRAN DISCUSSION—NEW METHOD FOR SUPPRESSING RATS.

PARIS, June 27, 1900.

NEXT Sunday, on the 1st of July, the Pasteur Hospital will open its doors and patients both rich and poor will be admitted free of charge, the first time such a plan of hospital treatment has been carried out in Paris. Hitherto all patients having an income exceeding 400 francs a year were obliged to pay a little over two francs a day in a medical ward, three francs and some odd centimes in a surgical ward, and five francs in a maternity. This hospital is a private institution, the money having been left anonymously for the founding of the same, a few months before Pasteur's death, in 1895. It is primarily intended for the reception of diphtheria patients. The architect chosen was Florentin Martin, and the great principles to be carried out in the organization of this hospital were the following: Complete isolation of each patient from the moment he entered the hospital; rigorous suppression of all danger of infection from his clothes; rooms and wards so disposed that they could be easily washed with water; an abundance of light, and hot and cold water in every room; lighting by electricity, and a modicum of furniture. One can safely say that the architect has taken advantage of all the ideas he could gather from an exhaustive visit to the principal hospitals of Germany, Austria, Switzerland, and Italy.

The patient, on arriving at the hospital, is shown into a special room, where he is examined by the physician. If he is found to be suffering from diphtheria or other contagious disease, he is shown into a "chambre d'entrée," and his clothes are taken from him and sterilized. A new suit of hospital clothes is given him, and he is taken to a "chambre d'isolement" and put to bed. Both rooms are disinfected as soon as the patient has left them. The "pavillon d'isolement" contains twenty-four rooms, containing each one bed, two wards for convalescents with twelve beds each, and five chambers with two beds, the latter being used for children accompanied by their mothers. The construction of the hospital is carried out on strictly scientific principles, stone and glass being used for the walls, and an empty space being left at one side of every room for the plumbing-pipes and electric-light wires. Hot-air pipes serve to heat the place. Instead of a director being appointed, Dr. Martin, who is the chief physician, has been made more or less general supervisor, and all the control is vested in the board of trustees of the Pasteur Institute, which meets every year.

A lively discussion has taken place recently at the Surgical Society regarding the use of ureteral catheterism as a means of diagnosing renal tuberculosis in its early stages, and its practical advantages in leading to an early intervention. The question was brought up for the first time in April, and since then it has been "on the tapis" at several meetings, but during the last three weeks the war of words has waged hot and heavy, and each side would seem to wish to have the last word. Dr. Pousson started

the discussion by reading a report of twelve cases on which he had operated with but one death. He stated that he had, however, never had occasion to operate on a case in its initial stages. Dr. Tuffier declared that ureteral catheterism was no means of giving assurance as to the condition of the other kidney. Dr. Albarran, who has used this method of exploration very extensively, took up the cudgels in its behalf and said he had never observed any accidents resulting from its use, when complete asepsis was enforced and the operator possessed a certain degree of manual dexterity. Dr. Tuffier answered that a discussion held two years ago in Berlin showed there was some danger in using this method, and chemical analysis of the urine passed and cryoscopy, or the examination of its freezing point, would often suffice to establish a correct diagnosis as to the condition of the other kidney. He was not in favor of an operation, unless the symptoms showed the general health was being affected. Dr. Albarran said it was to be remembered that cathe erization of twenty-four hours' duration was not called for, one hour amply sufficing.

On June 6th Dr. Bazy made a long speech, in which he showed how difficult cystoscopy might be under certain conditions, such as spasm of the bladder, strieture of the urethra, and youth of the subject. Desnos and Israel had cited cases in which accidents had occurred. He also expressed some doubt as to the advisability of catheterizing a healthy ureter after a diseased one had been investigated, washing out the bladder not being sufficient to ensure complete asepsis. Bazy strongly advocated the use of methylene blue, which is eliminated in a peculiar manner if both kidneys are affected. He has used this method almost exclusively, and said he considered catheterization not only a useless but a dangerous operation in many cases. As for operating upon renal tuberculosis in its early stages, Dr. Bazy said he was strongly opposed to it, just as much, for instance, as to castration unless the general health was affected. Of course hemorrhage was an important symptom, which could not be overlooked, and which might lead to an early intervention. He referred to a case in which Ricard had removed a very far advanced tuberculous kidney, on account of hemorrhage, but it was found that the hemorrhage came from the other kidney. If cystoscopy had been used, Dr. Ricard would have removed the relatively healthy kidney and the patient would not have survived.

On June 13th Dr. Albarran answered all that had been said against his first speech on the subject, and the gist of his remarks was that those who doubted the usefulness of this operation were those who had not employed it sufficiently to understand how easy it became through long practice. A week later another speech was made, this time by Dr. Bazy, and the observations of Dr. Albarran were more or less severely criticised. Nothing new can now be said on the subject, and it is to be hoped that the discussion has come to a close.

As rats have been shown to be in part the cause of the spread of plague, investigations are being carried out as to the best means of suppressing them. The *Matin*, a widely circulated morning paper, had an interesting article on this subject a few days ago. Dr. Danyez has been trying a new method at the Pasteur Institute, and as a result of his experiments this method was given a trial. A section of a sewer was closed in on both sides, two hundred large rats were placed in it, and they were fed with bread on which virulent cultures of a certain microbe had been deposited. Two weeks later only eight rats were found alive. In the bodies of the dead rats, which had not been eaten by the surviving ones, the lesions were found on examination to be always the same, and cultures gave the same microbe in all cases. These experiments have been carried out at Lille, at Tunis, at Copenhagen, and at Hamburg. The microbe used has no pathogenic action on other animals, and so one expeditious means of disposing of these rodents has been found.

LETTER FROM BRAZIL.

(From our Special Correspondent.)

SEPARATION OF XIPHOPAGOUS TWINS—THE PLAGUE.

São João del Rei, June 7, 1900

The medical world of Brazil was startled by the announcement that on the 30th ult., in the operating-room of the hospital of St. Sebastian in Rio de Janeiro, Dr. Chapot Prevost, one of Brazil's most distinguished physicians, had separated the eight-year-old twins, Rosalina and Maria, who had been the subject of much medical discussion during the past year, an operation that will mark an epoch in the annals of surgery.

These twins were born of poor parents in the state of Espirito Santo, Brazil, and were brought to Rio about a year ago. They were not united by a single band as were the Siamese twins, but their abdominal cavities were connected by a large opening, practically forming one cavity, their bodies being intimately attached as will be seen by the accompanying illustration. And as it afterward proved, the thoracic cavities were also implicated.

The following brief and incomplete account of the operation and history of the case up to the present may be of interest to the readers of the Medical Record. On June 23d of last year one of the leading Rio physicians made an exploratory opening, but finding the livers of the two girls so united as to form practically one liver he decided to go no further. Dr. Prevost then hearing of the case began a series of experiments to test the recuperative power of the liver, and the best means of controlling hemorrhage in this organ. Among others, he cut away a large part of a dog's liver, and in eight days it had almost reproduced itself. From these experiments he became convinced that this organ would bear a great deal of surgical interference, and he accepted the case.

Since last October the twins have been in this hospital under his care, and he has made a very careful study of the case from all points of view—anatomical, physiological, and psychological. He had several *x*-ray photographs

taken, and thus ascertained that the livers were united in nearly their whole extent.

While under his observation Rosalina had an attack of grippe, which lasted eight days, with a temperature on the third day of 40.2° C., with corresponding pulse and respiration, while Maria remained perfectly well. This confirmed him in his opinion that there were no psychological conditions to forbid their separation.

Having completed his studies and preparations he called a council of his colleagues who were to assist him, and explained to them his plans, and at 6 A.M. on the 30th ult. they assembled at the hospital to make the final preparations. Everything had been arranged with a view to the most perfect asepsis. The attendants, after taking a full disinfecting bath, dressed in new clothing thoroughly sterilized, and before entering the operating-room washed their hands and arms in six disinfecting solutions.

Before the operation the girls were given clysters of 500 gm. of artificial serum, and their bodies were thoroughly washed, first with soap and water, then with sublimate solution, and finally with sulphuric ether, after which they were wrapped in sterilized cotton covered with gauze. They were then placed upon a table especially prepared, which could be easily unjointed to make two, Rosalina lying upon her left side and Maria upon her right side, the cicatrix of the former operation showing upon the top.

The giving of the chloroform began at 9:15 A.M., and after slight resistance on the part of both they were soon

under its influence, and at 9:45 the first incision was made. This extended from the navel upward, having its middle at the ensiform cartilage, being closer to the false ribs of the right side of Maria. Turning back the flap toward Rosalina's side, the anterior superior surface of the liver was seen. This occupied two-thirds of the connecting space and formed a bridge between the two cavities. Below this was discovered another connecting bridge formed by the union of the two mesenteries. After having cut through the cartilage in the median line another bridge was discovered. This was formed by the union of the two pericardial sacs, 2 cm. in extent, through which the fluid could easily be seen passing from one sac to the other owing to the uneven beating of the two hearts. The operator placed a pair of pinces de Péan upon either side of this connecting bridge preparatory to separating it. This was one of the most intensely exciting moments during the whole operation, for by the severing of the anastomosing branch of the two mammary arteries the field of operation was deluged with blood. The points were quickly seized and the hemorrhage controlled, but one of his more fearful assistants inquired, "Doctor, will you still separate them?" He simply replied "Separo" ("I will separate"), and cut through the imprisoned tissue, and sutured the cut edges of each sac with catgut. Now, it was discovered that the pleura of Maria also extended across the line of union. However, before undertaking the task of correcting this it was thought best to attend to the mesenteric bridge, as its position made it easy for the intestines of one to pass to the cavity of the other. This was prevented by ligating it with silk at two points and cutting between them and returning the contents of each cavity to their proper place. He then returned to the remaining difficulty in the thoracic cavity. This was overcome by cutting upon the internal face of the half of the cartilage yet united, detaching the parietal pleura, and uniting it with a fine catgut suture to the median fold which adhered to the pericardial bridge.

Having thus completed the separation of the internal parts of the thorax, he then cut through the skin and cartilage on the other side, opposite to the first incision, leaving only the liver to be separated. This he accomplished in such a way as to give to each an uninjured gall bladder and duct. The final cut having been made at 10:50, and the table separated, he turned over Rosalina to two assistants, while he continued to care for Maria, who had suffered most from the operation. However, he had to suspend his work of closing up her wound to retie a ligature that had slipped from one of the hepatic vessels of Rosalina.

The final suturing was done on two planes, the deep peritoneal and the superficial, including the skin and muscular coat. At 11:45 the operation was completed. The condition of Rosalina was encouraging; that of Maria was much less hopeful. Little by little they were awakened, and upon opening her eyes, Maria, who awoke first, said, "Where is Rosalina." And Rosalina, upon awaking, asked the same in regard to her sister. When they saw each other, and realized that they were separated and still alive, Maria, looking toward Dr. Chapot, exclaimed, "Oh, doctor, how good you are!"—he had received his fee.

The children both vomited three times after the operation, and were given ice-water several times. Both during and after the operation they were given injections of artificial serum. They urinated without difficulty. After five o'clock they slept tranquilly with but slight interruption. At eight o'clock Rosalina wanted to say her prayers, and put on a new dress the doctor's daughter had given her. The following is the schedule of temperature, pulse, and respiration for the first twelve hours:

	Maria.			Rosalina.		
	Temp	Pulse.	Resp.	Temp.	Pulse.	Resp.
11:52 A.M.	36.0°	110	64	35.8°	Weak	45
3 P.M	36.7	126	46	36.6	110	38
5 P.M	36.6	128	44	36.6	108	42
8 P.M	37.3	126	43	36.9	112	39
12 M	36.6	130	48	37.2	124	40

On the second day, both slept well, though Maria, whose temperature ran up to 38° C. at 4 A.M. was somewhat disturbed. Her pulse at this time was 160, respiration 56; but at daylight these all had gone down somewhat. At 2:30 P.M. her temperature again ran up to 38.5°. She was then given injection of artificial serum and inhalations of oxygen, after which she became better, and at 9 P.M. was quietly sleeping. Rosalina remained in good condition all day, and several times asked to sit up.

Third day: During the night they both slept well, and during the day the general condition of both improved, and they closed the day in good condition, the temperature of neither going above 38.2°. At midnight Maria was given inhalations of oxygen.

Fourth day. Until 2 P.M. both girls were doing finely, when Maria's temperature ran up to 39, with pulse 172. She became quite weak and could not take nourishment. After taking inhalations of oxygen and a small dose of digitalin she became better. Her bowels were washed out, and she passed a large worm. At 9 P.M., temperature, 37.9°; respiration, 36; pulse, 150. At midnight both were sleeping, though Maria was somewhat restless.

Fifth day. The unfavorable symptoms of Maria of the day before did not return, and although very weak she was in every way better, taking with relish some broth at different times. The intestinal washings were continued with marked benefit. Oxygen was also administered throughout the day. The temperature did not get above 38.6°, and fell to 37.9°. Pulse, highest 150, lowest 137; respiration, highest 40, lowest 30.

Rosalina was in fine condition, she ate a little chicken and was anxious to sit up.

Sixth day: In the early part of the day Maria's condition was so flattering that the surgeon announced her to be out of danger. However, at 2:30 P.M. she began to vomit, and although this was checked, she became so prostrated that she could not rally under the supportive treatment given her, and at 1.30 A.M. of the following day she died.

At 3:30 P.M. the autopsy was held, at the request of Dr. Prevost, by the police physicians. He asked them to testify as to the following points, in addition to the regular facts of cause of death, etc.: (1) Had there been hemorrhage of the liver? (2) Had there been infection? (3) Was the death due to lack of skill, imprudence, or neglect?

The examination, made in the presence of a large number of physicians, revealed a state of inflammation of the pleura and pericardium with more or less exudate from each, but no inflammation of the peritoneum, while the liver was completely healed and cicatrized, as were all the external wounds. All present agreed that everything possible had been done that could have been done, but of course there were some who could find something to criticise, either in the method of operating or in the after-treatment. The experts have not yet made formal report.

Rosalina continues to improve without any drawback so far.

The report of this operation has made a great sensation in Rio, almost overshadowing the plague, which is yet extending itself throughout the city. However, there have been since May 16th up to June 5th but eighty-six cases with twenty-three deaths, which in a city of six hundred thousand inhabitants would indicate a very mild type. It is rumored that a case has developed in a city in the interior of the state of Minas, two hundred miles northwest from Rio, on the line of the Central Railroad of Brazil; but the rumor is not yet confirmed.

A Contribution to the Symptomatology of Senile Arteriosclerosis.—Friedmann rehearses the classical symptoms of this condition, and then goes on to describe a new sign which he considers of value in the diagnosis. Normally in adults the heart sounds are to be heard by careful auscultation over the descending aorta, and in health and under the age of forty to fifty years are most plainly appreciable at a point on a level with the spine of the scapula and just to the left of the vertebral column. With advancing years this point moves downward, and if, in addition, there is atheroma of the aorta the sounds are to be heard with great distinctness and force on a line joining the angle of the scapula to the spinous process of the seventh vertebra. The cause for this phenomenon is to be found in the fact, first, that these sounds are not truly transmitted heart sounds, the first being certainly purely vascular in its origin, for it is present even when over the aortic area the first sound is entirely replaced by a murmur; and, second, accompanying the arterial lesion there is nearly always a concomitant emphysematous condition of the thoracic walls which increases the resonating-power of the ribs and also causes an alteration in shape favorable for the direct transmission of the sound. There are also fixation of the chest in the expiratory position and prolonged and diminished expiration, which added to the hypertrophy of the left ventricle combine to make a set of causes sufficiently characteristic to give the sign diagnostic value. —*Wiener klinische Wochenschrift*, June 21, 1900.

Society Reports.

FIFTH DISTRICT BRANCH OF THE NEW YORK STATE MEDICAL ASSOCIATION.

Sixteenth Annual Meeting, Held in Brooklyn, May 22, 1900.

J. C. Bierwirth, M.D., of Brooklyn, President.

President's Address.—Dr. J. C. Bierwirth, in his address, considered "The Necessity and Benefits of More Completely Organizing the Medical Profession." The speaker pointed out the increasing frequency of malpractice suits, and the general feeling among the unprincipled that physicians are an easy prey owing to their sensitiveness and abhorrence of publicity. The liability of physicians to unjust arrest on mere suspicion of complicity in cases of criminal abortion was another crying evil. The remedy was to be found in proper organization, such as could be effected under the charter just granted to the New York State Medical Association. Believing in home rule, it was thought best that members should be admitted through their local organization, the county association, as here the character of candidates was best known. In time, the members would have not only protection from malpractice suits, but a death benefit fund. In conclusion, the speaker begged all interested in the welfare of the new and enlarged State association to put aside personal ambitions and differences, that all might work shoulder to shoulder for the common weal.

The address was ordered printed and distributed gratuitously to the regular physicians of the State.

Discussion on Diabetes.—The afternoon was devoted to this symposium.

The Identification of Dextrose in Human Urine.—Dr. Heinrich Stern presented an elaborate paper on this subject, which he read in abstract. He said that while, as a rule, glucose could be identified in urine containing 0.5 per cent. or more of it, great difficulty was experienced when the quantity was less than this. He knew of a number of instances in which persons had undergone treatment for diabetes without ever having suffered from this disease. Many spurious cases had come under his observation which had been diagnosticated as diabetes by life-insurance companies. He was cognizant of many errors which had been committed in testing for glucose, which would never have occurred if the physician had taken the precaution to make use of control tests. Mention was made of a case in which a diagnosis of glycosuria had been made in a person who had indicanuria. The explanation was to be found in the fact that the physician who had tested the urine had employed only the bismuth test, and had fallen into the error because the bismuth had been reduced by the indican. Grape sugar may be confounded with a number of other urinary constituents. Comparing the more important of these tests, it would be found that with Boettger's test the limit of sensitiveness was one per cent., and the limit of reliability 0.5 per cent.; with Nylander's test, 0.1 per cent. and 0.3 per cent. respectively; with Trommer's, 0.1 per cent. and 0.5 per cent.; with the fermentation test, 0.1 per cent. and 0.5 per cent., and with the phenylhydrazin test the limit of sensitiveness was 0.03 per cent., and limit of reliability 0.05 per cent. The delicacy of the glucose test, moreover, was not the same in all urines. For instance, Trommer's test was exceedingly delicate if skilfully applied to certain urines, yet in a great majority of instances it could not be relied upon when there was less than 0.5 per cent. of glucose present.

Boettger's Bismuth Test: Excessive amounts of pigment, glycuronic acid, mucin, and other urinary constituents containing sulphur, gave a reaction similar to that obtained with glucose. Almost every urine blackened bismuth in a strongly alkaline medium, but the darkening was not due to sugar. Saccharin was one of the substances which prevented the reduction. The working of the test was interfered with in urine containing antipyrin, acetanilid, salicylates, quinine, sulphur, mercurials, salts of iodine, turpentine, senna, tannic acid, chloral hydrate, benzol, sulfonal, trional, and many others.

Trommer's Test: This test was interfered with by the presence in the urine of uric acid, urates, creatin, hippuric acid, indican, nucleo-albumin, urinary pigments, glycuronic acid, arsenic, tannin, gallic acid, pyrogallol, camphor, copaiba, cubebs, chrysophanic acid, salicylic acid, oxalic acid, chloral hydrate, turpentine, glycerin, sulfonal, thallin, benzoic and carbolic acids. Albumin, parapeptone, salts of ammonium, and saccharin retarded or prevented the reduction. Urine rich in ammonia might keep the cupric oxide in solution.

Phenylhydrazin Test: The delicacy and trustworthiness of the phenylhydrazin test, the speaker said, had been decidedly overestimated. The true nature of the crystals must be demonstrated beyond a doubt before the reaction could be considered positive.

Picric Acid: This test was very fallacious.

Fermentation Test: The fermentation test was one of the most reliable methods of detecting the presence of grape-sugar in human urine. The test was made with fresh beer yeast, or with German yeast. The method of determining the quantity of sugar by the amount of gas generated must always be very inaccurate. Roberts' method—the determination oft he loss in specific gravity by fermentation—was a very reliable one, and was well suited to the needs of the medical practitioner. But there was not a single method of determining the presence of glucose in urine that was not open to sources of error; hence absolute reliance should not be placed in any one of them alone. The employment of the copper test in mere routine work without a control test was certainly objectionable. The speaker asserted that one case in every six or seven coming to him was neither diabetes nor glycosuria, yet the urine in the majority of them gave a reduction with the copper tests.

Diabetes Mellitus in Children.—Dr. Henry Dwight Chapin considered this subject. He said that the literature was almost silent on diabetes in children. A case had been reported in 1895 in which glucose had been found in the liquor amnii of a pregnant woman suffering with diabetes, in which examination of the infant's urine failed to show any glucose. Dr. Chapin reported two cases seen by him during the past year. The first was that of a boy aged four years and a half, who, following the fatigue and exposure caused by the Dewey parade, had developed a slight fever and had rapidly lost flesh and strength. Dr. Jackson, on being called in, had found that the child was passing over one hundred and five ounces of saccharine urine daily. He had failed to find, on careful examination, with Dr. Jackson, any evidence of tuberculosis or other organic disease that might explain the atrophy. The disease lasted about three weeks, the child dying three days after he saw it. The other case had been seen in consultation with Dr. McPhee, and was that of a boy aged about six years, in whom the disease ran about the same course. The patient was in semi-stupor at the time of the examination, but this had deepened into coma, in which state the boy had died four days later. In both of these cases the urine had contained about five per cent. of sugar, which had persisted to the last. The extremely rapid emaciation was specially worthy of note. Dr. Chapin said that

he had made it a practice to have the urine of his hospital children systematically examined, and it had been very rare to meet with glycosuria. It was exceedingly fatal in early life.

Diagnosis, Symptoms, Treatment, and Prognosis of Diabetes Mellitus.—Dr. Egbert Le Fevre read a paper with this title. He said that the peculiarly aged and emaciated appearance of diabetics was quite characteristic. These patients did not present an anæmic condition of the mucous membranes. The onset of the disease was frequently insidious, and the diagnosis often was first made by a life-insurance examiner. Ordinarily, the only thing noticed at first was a slight loss of vigor or of general health. The occurrence of thirst and the increase in the quantity of urine were frequently so gradual as not to attract attention. The manner of onset often determined the subsequent course of the disease. In the aged and in stout people from sixty to one hundred ounces of urine might be passed. When the night urine was equal to or greater than that passed during the day, it was to be considered an unfavorable sign. Polyuria with a decrease in the quantity of sugar was always a good sign. The color of the urine was usually pale or light yellow; a greenish or greenish-yellow tint was an unfavorable sign. Dark-colored urine, or a sudden increase in the color, should lead one to estimate the presence of sugar or its quantity, as this change in the color often occurred just before an attack of coma. The specific gravity usually ran parallel with the percentage of sugar contained. A low specific gravity, however, did not preclude the presence of sugar, as a few cases had been reported in which sugar was found in urine having a specific gravity of 1.012. A light-colored urine having a specific gravity of 1.025 should always be examined for sugar; a high-colored urine having a specific gravity of 1.025 or 1.030 was of little significance. The diurnal variation in the amount of sugar was of great importance. If the quantity of sugar passed during the night exceeded that voided during the day it indicated that the disease would run a severe course, and would rapidly prove fatal. Every case would be limited, to a greater or less extent, by the quantity and character of food taken. The occurrence of phthisis caused a reduction in the quantity of sugar. When diabetes was associated with advanced disease of the kidney there was likely to be a progressive diminution in the quantity of sugar, so that this was not necessarily a favorable symptom. Most authors stated that the quantity of urea was increased in diabetes. This was usually due to the exclusion of the carbohydrates and the patient's being on a largely nitrogenous diet. The quantity of urea became less than normal in the terminal stage. When uric acid was present in diabetic urine, and the latter had a high color, it usually indicated a mild type of the disease. It was most commonly observed in gouty people. A small trace of albumin in the urine was an almost constant symptom of diabetes. In the large proportion of cases showing this small quantity of albumin there were no other evidences of nephritis. In diabetic coma albumin was always present, and as the sugar often decreased or disappeared on the occurrence of coma, many of these cases had been erroneously looked upon as examples of uræmic rather than of diabetic coma. Diacetic acid was never found in normal urine. In the diabetic it was readily produced by the withdrawal of carbohydrates. Gerhardt's test for diacetic acid was exceedingly simple. It was applied by adding to the urine a strong solution of perchloride of iron. If this caused a deep wine color, it indicated the presence of diacetic acid. In answer to the question as to whether the diagnosis of diabetes could be more surely made by an examination of the blood than of the urine, the speaker said that it was, to say the least, a most useful method of examination, as the reaction with the blood was often observed when it was no longer obtained in the urine. One of the simplest of these tests was that known as Williams', which consisted in adding a small quantity of blood to a measured quantity of a standard solution of methylene blue, and noting if any decolorization took place. The peculiar sweet, aromatic odor of the breath was often of more or less diagnostic import, and was especially apt to be present just prior to the occurrence of diabetic coma. Of the nervous manifestations the most important were the mental derangements. The diabetic was never cheerful, not even when the diabetes was complicated with pulmonary tuberculosis. The patellar reflex was diminished in the majority of cases of diabetes, and when occurring in an early stage this was an unfavorable sign. The most common cause of death in diabetes was coma. It was most common in those who rapidly emaciated, and the most frequent exciting causes were mental excitement, fatigue, and sudden indiscretions in diet. Severe pain in the epigastrium, with or without nausea, was an exceedingly common precursor of diabetic coma. In these cases albumin was always present, generally in large quantities, and whitish specks would be found frequently floating in the urine. The latter were found, on microscopical examination, to be collections of casts. The mild form of diabetes was usually the result of errors in diet, and was associated with obesity. The second form was the arthritic or gouty, and often constituted only a transition from the obese to the severe form of diabetes. A third type was the neurotic. These persons were generally spare and nervous, and such cases were apt to be characterized by transient glycosuria for some time before the true diabetes was established. Under proper management these patients enjoyed good health and the disease could be controlled for a long time. The severe type was characterized by a sudden onset and rapid emaciation, with loss of muscular power. In the well-to-do the disease was often mild; in the poor and hard-working the disease was severe, and its course was rapid. Von Noorden had made an excellent suggestion concerning the method of testing the sugar-destroying power of the individual organism. This the speaker had carried out by giving in the morning, before breakfast, 150 gm. of grape sugar, and following this shortly afterward by the usual breakfast. The patient remained in bed during the test. If the urine showed no glycosuria the dose was gradually increased up to one of 250 gm., and if this failed to produce transient glycosuria it was fair to assume that the sugar-destroying power of the system was within the normal limits. A case was cited to show the valuable aid such a test was capable of rendering. In regard to treatment the speaker thought the tendency had been to go to extremes in the matter of diet. If with a certain diet the sugar diminished in quantity, and yet the patient's general condition was not correspondingly benefited, or was even made worse, this was a distinct indication that the dietary was wrong. The quantity of urea excreted should be determined from time to time. Another useful guide in regulating the diet was testing the urine for diacetic acid. He had been unfortunate enough to see three cases of diabetic coma within the past five months, in which the patients had used a certain combination of arsenic freely advertised and now quite popular for such cases. These patients had shown a temporary diminution in the quantity of sugar in the urine, but the remedy had caused gastro-intestinal disturbance, and he believed it was dangerous. This remedy had one deceptive feature: it was apparently well tolerated by the patient, though in reality it was insidiously mischievous.

The Relations of Surgery to Diabetes Mellitus.—Dr. Charles P. Gildersleeve contributed this paper to the discussion. He said that the text-books on surgery gave very little information on this subject. Many of them, especially the older ones, insisted that wounds in diabetics were prone to become gangrenous, but this assertion was disputed in some of the more recent works, the contention being that, with antidiabetic diet and thorough antisepsis and asepsis, this should not occur. The author did not think it could be denied that in some instances gangrene occurred in diabetics apparently from no other cause than the existence of the diabetes. Cases were cited in support of this view. One of the most striking of these was a case of rapidly fatal gangrene developing in a man upon whom he had operated for phimosis. This man stated that he had been diabetic for several years, yet his health had been such as to allow of his going around as usual. When the flaps sloughed in these cases the healing-process would be found to go on with exceptional rapidity under the use of charcoal poultices. In the management of these cases surgically he was guided by the following rules: (1) He would not operate upon any patient suffering from diabetes without explaining the possible dangers; (2) he would not operate for benign tumors or other simple conditions unless there was some special reason for so doing; (3) for the rapidly spreading gangrene occurring in these cases, and which was bound to cause death if left alone, he believed in prompt and high amputation.

Ocular Manifestations in Diabetes Mellitus.—Dr. L. A. W. Alleman took up this part of the subject. He said that ocular lesions were more frequently found in the chronic cases with mild general disturbance. Paralysis of the extra-ocular muscles in both mild and severe cases of diabetes, and in persons unaware of the existence of any serious disorder, were not uncommon. Any of the extra-ocular muscles might be involved. Paralysis of accommodation was perhaps the most common of the ocular manifestations of diabetes, and occurred quite early. The paralysis was often complete, so that the patients would observe perhaps only increased difficulty in reading. Some authors claimed that there was a true diabetic cataract, while others contended that the changes in the lens were no more common in diabetics than in others of the same age. But the unexplained occurrence of juvenile cataract required an examination of the urine in addition to the physical examination. Hirschberg believed that there was a true, distinctive diabetic retinitis, and the speaker was disposed to agree with him, though this view was not accepted by many. A diabetic retinitis might take on a renal character when disease of the kidney developed in a diabetic. Retinal hemorrhages, with or without other retinal changes, were always suggestive of diabetes, particularly the small, punctate hemorrhages. They were always associated with conjunctival hemorrhages. Retinal changes were always present in a case of diabetes which had existed more than ten or twelve years. While this was always an unfavorable symptom, it did not necessarily indicate an immediate termition of the disease. Iritis of a severe type was often met with in diabetes.

Cutaneous Manifestations in Diabetes Mellitus.—Dr. Samuel Sherwell discussed this topic. He enumerated the more important cutaneous manifestations as follows: (1) xeroderma, a condition of dry skin which was almost always present; (2) pruritus without any noteworthy subjective lesions, the genital region suffering most; (3) eczema, partly neurotic, and at other times catarrhal, having its chief seats on the genital and flexor surfaces of the body; (4) furunculosis, often general in character, but sometimes regional; (5) conditions of an erysipelatous nature, and gangrene—usually late symptoms; (6) xanthoma diabeticorum, accompanied by immense numbers of new growths; (7) the recently recognized disease named blastomycetic dermatitis; (8) the disease termed dermatitis herpetiformis, or Duhring's disease. Dr. Sherwell said that the only cases of erysipelas of the upper air passages that he had met with had been in diabetics. Some striking photographs of a case of xanthoma diabeticorum were exhibited. In this case the improvement in the cutaneous lesions had been most remarkable after dietetic treatment continued for only a fortnight.

Manifestations of Diabetes Mellitus in the Upper Air Passages.—Dr. Jonathan Wright spoke on this subject. He referred to a case of glycosuria developing suddenly after a third nasal operation on a boy aged fifteen years. This glycosuria had disappeared under a few months of hygienic and dietetic treatment. Extended reference was then made to Dr. W. Freudenthal's recently published five cases of ulceration of the upper air passages in diabetics, and the opinion was hazarded that Dr. Freudenthal had not positively excluded tuberculosis and syphilis. There was still another class of throat cases in which it had been claimed diabetes was more than ordinarily frequent, *i.e.*, in cases of laryngeal vertigo. He had examined the reports of these twenty or thirty cases, and had found diabetes present in only three of them. As these three were all plethoric persons over forty years of age, it did not seem to him that it had been proved that there was any larger proportion of cases of diabetes among them than among other individuals.

Dr. Nelson L. North said that he believed that some emotion or serious nervous disturbance was almost always the exciting cause of diabetes, and that the disease was essentially a failure of the digestive and assimilative processes brought about by this profund nervous influence. He had been impressed with the part played by heredity.

Dr. Heinrich Stern, in closing the discussion, said that of the two hundred and six deaths from diabetes reported in the boroughs of Manhattan and the Bronx in 1899, fifty-eight had occurred in coma. Of fifty cases of diabetic coma that he had studied, fully fifty per cent. had shown no excess of acetone, or the presence of aceto-acetic acid. To his mind, diabetes mellitus was only one stage of a progressive disease characterized by the elimination of glucose and urea. He recognized in all three stages, viz., (1) a preglycosuric stage; (2) a glycosuric stage—diabetes mellitus, and (3) a postglycosuric stage, or a stage of toxæmia arising from the action of ethyl-diacetic acid.

AMERICAN PROCTOLOGIC SOCIETY.

Second Annual Meeting, Held in Washington, D. C., May 2 and 3, 1900.

First Day—Wednesday, May 2d.

President's Address.—The president, Dr. Joseph M. Mathews, of Louisville, said that the bane of specialism of to-day was the "blooming out" of a class of men to practise specialties, who had no practical knowledge of them. Such action should receive the strongest censure from the entire profession. He took it that the object of this assemblage was mainly to encourage the better understanding of the diseases of the rectum, by the reading of papers and the free discussion of the same. If permitted, he would suggest that the membership be made up of those who desire a better knowledge of proctological subjects, whether general or special surgeons, gynæcologists

or obstetricians. Indeed, it was by the diffusion of such knowledge in a general way that societies were of profit. Considered from a special standpoint, it might be well to try to demonstrate that it was just as difficult to excise a rectum as it was to remove an ovary; that it required as much surgical knowledge to anastomose the colon around a stricture as it did to sew up a lacerated perineum; to do a colopexia as to remove a fibroid tumor; or to do a colostomy properly as to do a trachelorrhaphy.

Report of a Case of Excision of the Rectum through the Vagina.—Dr. S. T. Earle, Jr., of Baltimore, reported this case, which was one of adeno-carcinoma; there were about five inches of the rectum removed. The centrifugal end of the rectum was drawn down, and stitched to the anal margin; the vaginal and perineal incision was closed, and united by first intention. The results were most satisfactory, and the patient had fair control of her evacuations.

Unique Cases of Rectal Surgery.—Dr. Samuel G. Gant, of New York, reported these cases.

Case I.—Congenital absence of the coccyx and lower sacral vertebra. This patient was referred to Dr. Gant to be treated for anal fissure. He was thirty years old and a very strong man. Examination revealed the absence of the coccyx and lower sacral vertebra, which made the broad end of the bone stand out and be easily noticeable through the skin because of the fact that the tissues below it were drooped, making a concavity large enough to hold a goose-egg. He had been that way since birth, but had suffered no inconvenience from it, having perfect control over his bladder and anus. The fissure was relieved by divulsing the sphincter, incising the rent, and stimulating it thereafter with a mild silver solution.

Case II.—Stricture of the rectum in a little girl eleven months old, caused by swallowing an open safety-pin. This case was of unusual interest because of the child's age. At the time the pin was swallowed it caused considerable pain and suffocation. It was passed embedded in a mass of fecal matter just one month later. Several days preceding this she suffered great agony and passed frequent and bloody stools. From this time on the child continued to have bowel trouble, suffering from constipation, occasional diarrhœa, and the discharge of pus, blood, and mucus with the stools. Digital examination revealed a tight stricture three inches above the anus which appeared to be the result of inflammatory action and adhesions. It was easily dilated with first one and then two fingers. The ulceration was curetted, the rectum irrigated, and the patient sent home. After-treatment consisted of stimulating applications and occasional divulsion with the finger. This patient was discharged cured in eight weeks.

Case III.—Closure of artificial anus of more than three years' duration. The left inguinal colostomy was made in the case of a young woman eighteen years old, suffering from tuberculous ulceration which would not succumb to less radical means. As a result of treatment, local and general, she fully recovered in a year, having in the mean time supported herself as a waitress. She desired the opening closed, but she was advised to wait. Three years from the time the operation was made, she became engaged to be married and insisted upon the closing of the opening in the side. Thorough examination demonstrated that the ulceration had healed, and further that there was no constriction of the bowel. A No. 10 Wales bougie passed through the anus and out at the anal aperture in the groin. The opening was included in two elliptical incisions which were carried inward until the bowel was separated from the parietes. Because of the spur both legs of the original loop were firmly adherent and required resection. A purse-string suture was thrown around each, a Murphy button inserted and locked, and the gut dropped into the abdominal cavity. Peritoneum, muscles, and skin were united with catgut. Primary union obtained; the button passed on the tenth day, and the patient left the hospital at the end of three weeks. This patient made a complete recovery. She was under observation for two years after the closure, and her bowels moved naturally during this time.

Submucous Ligature for Hemorrhoids.—Dr. B. Merrill Ricketts, of Cincinnati, read this paper. He said that in performing this operation a large needle was made to describe more than a semicircle, carrying a moderate-sized kangaroo tendon submucously around the varices which occupied the rectum as much as three inches above the muco-cutaneous border. The three hemorrhoidal vessels, arterial and venous, entered the rectum and perforated the rectal muscular tissue about three and a half inches above the sphincter ani. Great difficulty had been experienced in passing the needle to complete the entire circle submucously. To overcome this the needle was brought out at a point corresponding to one-half of the circle, again to enter at its point of exit, and then made to pass out at the point of primary entrance. In cases of but one or two hemorrhoids one ligature of this character was sufficient. If there were many hemorrhoids occupying the entire circumference of the rectum as many of these submucous ligatures might be applied as necessary. Then, too, it was not necessary to incorporate all the varices within the ligature, because many of those which were not so constricted by the ligature would become so as a result of the trophic changes which ensued. Sometimes it would be found most convenient to introduce all the ligatures before making them taut. By doing this the introduction of the needle was made with greater ease. Before this work was attempted the sphincter ani should be divulsed to the fullest degree with the finger. Divulsion once being completed, the hemorrhoids would at once protrude, and were most easily encircled by the ligature. As soon as the ligatures were made taut the hemorrhoids were inverted into the rectum. Sometimes it was desirable to puncture some of the larger hemorrhoids that the distention might not be so great, and for the purpose of lessening the amount of hyper trophied tissue within the rectum. After a few weeks atrophy would have taken place to such a degree as to allow the sphincter ani to resume its normal tonicity, and to have completely destroyed all the objectionable varices which formerly existed. The advantages of this operation were, (1) the impossibility of secondary hemorrhage; (2) there was no tissue destroyed or sacrificed; (3) the loss of time was but little, if at all, greater than when the growths were removed by the clamp and cautery; (4) thus far there had been no infection; (5) there had been no fistula, abscess, or fissures resulting therefrom; (6) the pain was no greater, and perhaps less, than with other methods of ligaturing; (7) there was absolutely no stenosis.

Temporary Artificial Anus.—Dr. James P. Tuttle, of New York, read this paper. He said that the indications for temporary artificial anus were: (1) Obstruction with removable cause; (2) in cases of excision of the rectum in which the sphincter was involved; (3) in intractable ulceration of the rectum; (4) in stricture of the rectum with large area of ulceration which did not readily yield to local treatment; (5) in neoplasms in the sigmoid and colon that could not be found through the rectum; (6) in malformations and imperforate rectums, in which the gut could not be easily found in the perineum; (7) in chronic membranous colitis; (8) in certain forms of recto-vesical, recto-vaginal, and recto-urethral fistulæ. With these numerous and clear indications, the operation was

comparatively seldom recommended because of prejudice against it, and the false impression that once one had an artificial anus he must always have it. Doctors hesitated to advise it, because they knew that by the older methods closure was uncertain, and more dangerous than the operation or the disease for which it was made. The operation advised was a modification of the Rectus-Maydl method. It was quick, simple, and effectual. The opening was a T-shaped incision so made that the transverse flap fell into the distal, and effectually closed it, while the two triangular ones rolled outward and curled up like a dry leaf, thus leaving free exit from the proximal leg of the convolution. No part of the gut was removed or destroyed. The closure was made by simply unrolling and suturing these flaps back into position, first with sutures through the mucous membrane and then with Lembert sutures of chromicized catgut. After the gut was thus closed, the partial parietal peritoneum was dissected away for an inch or more all around the abdominal incision, so that the gut would drop back into the abdomen, but not into the peritoneal cavity, thus eradicating the spur. The muscular fascia and skin were then sutured over the gut with silkworm gut.

Chronic Interstitial Proctitis as a Factor in Obstinate Constipation and its Radical Treatment.—Dr. J. Rawson Pennington, of Chicago, demonstrated that the sigmoid flexure in the distended state frequently extended into and occupied the right iliac fossa; he also gave conclusive evidence of the existence of the rectal valve and its structure. He claimed that deformity of the rectal valve and hypertrophy of its muscular layers were the two principal primitive causes of obstinate constipation. He exhibited his automatic valve clip for dividing these structures when pathological.

Demonstration of the Rectal Valves in the Living Subject.—Dr. Thomas Charles Martin, of Cleveland, Ohio, showed his method of proctoscopy. Without the use of an anæsthetic, by means of his chair the subject was put into a posture equivalent to the knee-chest posture, the rectum inflated, and its entire length exposed to direct view. The rectal valves were rendered conspicuously visible and palpable to the members of the society, and the fact of their existence was generally admitted.

Second Day—Thursday, May 3d.

The New Radical Operation for Valvular Obstipation.—This was described by Dr. Thomas Charles Martin, of Cleveland. He said that a normal valve might be effaced under the pressure of the test-hook. A valve situated on the fixed posterior wall of the rectum was much more obstructive than was one situated on the anterior wall, for the reason that the descent and backward excursion of the anterior rectal wall placed the fæces more securely in the pocket afforded by a posterior valve. A valve situated on the anterior wall, if of the same condition and dimension as one situated on the posterior wall, was less obstructive to defecation, for the reason that the backward and downward excursion of the rectal wall threw the fæces out of the valve pocket and over its free border. If the number of the valves was greater than the normal three, it could be readily understood that such an addition increased the obstruction. For instance, four or five relatively shallow valves placed close together were more obstructive than were two somewhat deeper valves if these two valves were placed at some distance from one another. Anatomical coarctation or physiological juxtaposition of the valves might contribute to the establishment of obstipation whether the valves were diseased or not. If two valves were so closely situated that their borders were seen to overlap, or if it was seen that on the patient's bearing down two valves then overlapped, it might be assumed that these valves constituted an obstruction to defecation. A valve situated at a direct right angle to the axis of the rectum was more obstructive than one that was obliquely situated. However, an oblique valve might contribute to the establishment of an obstruction in a transverse valve immediately below it, for the reason that the oblique valve might deflect the fecal column directly into the pocket formed by the next lower and transversely situated valve. The resistance which any given valve afforded to the test-hook, the propinquity of other valves to a given valve, and the direction of the valve next above a given valve, together with the number of valves in the rectum and the precise situation and direction of each valve, were all features which should be studied as possible component factors which contributed to the obstipation. Hypertrophy of the rectal valve due to a proctitis, local or general, was characterized by evident thickening of the free border of the valve. Fibrosis of the rectal valve was not characterized by an increased size of the valve, though its resistance to the hook might be as great as in the case of the hypertrophied valve. There was always noticeable in cases of valvular obstipation a very conspicuous redness of the mucous membrane, which began at the obstructing valve and extended downward toward the anus. The rectal mucosa above the obstructing valve was usually of pale complexion except in those cases in which there was invagination of the upper gut. Dr. Martin then outlined his operation for division of the valve, and detailed the precautionary measures to be employed to insure safety and secure success.

Mooted Questions in Proctology.—Dr. A. B. Cooke, of Nashville, called attention to a number of the more prominent points of disagreement among proctologists. These were: (1) Anatomy: the existence of the rectal valves was not yet generally admitted, when in truth they constituted the most conspicuous features of the normal rectum. (2) Physiology: many points in this connection were yet to be worked out. The mechanism of defecation was a much-disputed subject. (3) Pruritus ani: was this a disease or merely a symptom? The etymology of the term itself offered the readiest solution of the problem. Pruritus meant simply itching, and itching could not be regarded as other than a symptom. Though sometimes difficult to locate, the lesion which gave rise to it was practically always a macroscopic one. In searching for it the reflexes were to be borne in mind. (4) Simple ulceration: one prominent author (Mathews) stated that this disease located above the sphincter ani muscle was a very uncommon one. Dr. Cooke's experience had been the very opposite. The difference of opinion is probably due to different conceptions of the meaning of the word; properly considered, ulceration and ulcer were synonymous terms, and the rectal ampulla was a frequent site of such disease process. (5) Benign stricture: the author called attention to the different views held as to the frequency of syphilis as a causative factor. Sixty per cent. is far too high an estimate. The rectal valves have much to do in the etiology of this disease. (6) Cancer: discussion of this disease was limited to the question of the justifiability of colostomy as a means of prolonging life and giving comfort. As compared with the hypodermic syringe the author deemed it greatly to be preferred, and when total extirpation was impossible he strongly advised resort to this procedure.

Pruritus Ani, with Especial Reference to its Local Treatment.—Dr. Lewis H. Adler, Jr., of Philadelphia, read this paper. He said that it was important that the patient had a daily evacuation of the bowels, and, if necessary, medicines were to be

used for this purpose. In all cases, more or less varicosity of the hemorrhoidal vessels existed; at all events, he was in the habit of seeing the patient daily for a time, and he employed an injection into the cavity of the rectum of one, or two, or two and a half drachms of the following prescription: ℞ Fluid extract of hamamelis, fl ℥ i.; fluid extract of ergot, fluid extract of hydrastis, compound tincture of benzoin, āā fl ℥ ii.; carbolized olive or linseed oil, fl ℥ i. (carbolic acid, five per cent.). M. S. Shake well before using. The patient was advised, prior to using this injection, that a desire to have the bowels evacuated would occur as a result of its employment, but that if he would remain quiet upon the examination table, the sensation would quickly pass away. The entire surface around the anus for several inches outward was to be painted with a strong solution of nitrate of silver. If any break in the continuity of the skin existed as a result of previous scratching, a little of a two-per-cent. cocaine solution applied to the abrasion would prevent the suffering incident to the use of the silver salt. In his experience the use of a strong silver solution was not nearly so painful, under the circumstances surrounding its use in the class of cases under consideration, as the weaker solutions. So soon as the silver had dried and from the first visit and thereafter, the officinal citrine ointment or unguentum hydrargyri nitratis was smeared over the anus and the cutaneous surface of the parts for a distance of about two inches around the orifice. The ointment was used in its full strength. Over the salve was placed a wad of absorbent cotton, the quantity of cotton varying with the patient's wishes and comfort. The dressing was kept in place with a T-bandage. If the itching should annoy the patient during the night he was directed to bathe the anus with hot water, as hot as could be borne with comfort, but under no circumstances was he to rub the parts. He was also told that the application of the hot water would momentarily increase the itching, but that he was not to scratch. After he had used the water he was directed to use either a solution of black wash (lotio nigra) or, what was better in some cases, calomel ointment, either of which was to be applied locally to the affected parts.

Fistula.—Dr. George B. Evans, of Dayton, Ohio, read this paper. He said that the inefficacy of all remedial measures except the knife for curing fistula still remained unquestioned, unless by inaccurate observers. A fistula which was not due to ulceration and perforation of the rectal wall from within was the result of a previous abscess, due to an inflammation, and that the result of traumatism. He had sometimes found fistula due to caries of the lower portion of the sacrum and coccyx. He believed it to be a safe rule to operate on phthisical patients as upon others. During the past ten years there had been over six hundred phthisical patients admitted to St. Elizabeth Hospital, Dayton, Ohio; during the past six years he had operated upon one hundred and ninety-eight cases of various rectal diseases in the charity wards, of which forty-two had been for fistula; seven of the forty-two had been without doubt tuberculous. Two of the seven patients died after several months of comparative comfort.

Silver Leaf has been used in the Johns Hopkins and Bellevue hospitals as a dressing for burns, with satisfactory results.

Strangulated Hernia.—The parts about the tumor should be covered with vaseline, the patient placed upon the back, with the pelvis elevated and thighs flexed, and ether be poured or sprayed upon the constricted neck. This depletes the tissues and permits of reduction, previously impossible.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 9, 1900.

Eugene Hodenpyl, M.D., President.

A Case of Tubular Cast of the Bronchus.—Dr. Theodore C. Janeway presented this specimen. It had been coughed up by a middle-aged and very stout gentleman who had been sick for about ten days with what had been supposed to be the grippe. He had been apparently convalescent, when he had been suddenly seized with dyspnœa and increased fever. After some hours he had expectorated this cast, which was perfectly tubular and of about the size of the main bronchus. At its lower end it showed the beginning bifurcation into the smaller bronchi. The specimen not having been seen until it had been immersed for some time in alcohol, no cultures had been made. The man died a few days later, having exhibited signs indicative only of bronchitis with marked dyspnœa and cyanosis. On section, the cast showed a fibrinous exudate with numerous cell nuclei. Scattered through it were clumps of round-ended bacilli, which in their morphology and staining exactly resembled diphtheria bacilli. The speaker said that two cases had been reported before the London Pathological Society. One of these had been reported by Dr. Pye Smith in 1880. In this instance a woman had expectorated a cast of the trachea and primary bronchi. At the autopsy the trachea and bronchi were found lined with tubular casts. Rod-like bacteria were present. The other case had been reported by Dr. Murchison. A prominent laryngologist had seen the case just reported, so it seemed safe to assume that no evidence of diphtheria had been visible during life, though it was apparently a case of diphtheria of the bronchi.

Dissecting Aneurism of the Aorta.—Dr. H. S. Carter presented this specimen, which had been taken from a man aged eighty years, who had died some months ago in Bellevue Hospital from chronic interstitial nephritis. At the autopsy the condition in the aorta had been discovered accidentally, and for this reason the specimen was not in perfect condition. The dilatation of the aorta started from the sinus of Valsalva. The dissecting aneurism began at the junction of the descending part of the arch and thoracic aorta and continued through into both common iliacs. The left suprarenal was given off directly from the aneurismal sac, as was also the inferior mesenteric artery. Dr. Carter said that up to 1856 only eight cases had been reported; up to 1895 there had been seventeen, and by 1897 two hundred cases had been collected, including all dissecting aneurisms, but the greater part of these had been of the arch of the aorta. There was only one case on record in which the diagnosis had been made during life, and this had been confirmed by autopsy. It should be noted that the history of these cases had been pretty uniform—a history of sudden pain in the chest and back and shooting into the abdomen, but not radiating down the arm as in angina pectoris. There was also a feeling of something having given way. If the patient did not die immediately, there were œdema and other evidences of disturbed circulation.

Dr. James Ewing said that he had studied the specimen a good deal. At first it had appeared to be a case of true double aorta, largely because of the large vessels given off unquestionably from the aneurism. Though not familiar with the literature it seemed to him rather difficult to explain the separation of a trunk of the size of the inferior mesenteric from the aorta, and the subsequent canalization that had undoubtedly taken place in this case, if it was one of dissecting aneurism. A strong point in favor of dissecting aneurism was the presence of three openings

at the top of the sac. He asked if Dr. Carter had seen in his reading any description of the manner in which these large vessels were given off.

Dr. Carter replied that in looking over the literature of the subject he had found a number of similar specimens reported, particularly descriptions of the inferior mesenteric given off from the aneurismal sac.

A Case of Non-Traumatic Rupture of the Heart.—Dr. N. B. Potter presented this specimen, which had been removed from a large, stout woman, admitted to the City Hospital on February 28th. According to the history she had suffered for five or six years from bronchitis and asthma. Some time in last November a bronchitis had become more than usually troublesome, and she had begun to complain of pain in the left side and back, radiating to the shoulder and down the arm. When first seen by him on March 1st, she had been pale and cyanosed, and there had been much cough and expectoration. The physical examination had revealed nothing further than a diffuse bronchitis. The heart sounds were rather feeble. In spite of stimulation she became gradually more cyanosed, and finally died, about two weeks after admission. At the autopsy the pericardium had been found fairly full of blood, much of which was old and clotted. It was estimated that this represented about twenty ounces. A rupture was found in the left ventricle, a short distance from the interventricular septum. On the ventricular side was a large thrombus attached at the superior extremity. It formed a sort of valve and occluded the opening. Apparently the rupture had taken place some days before death. The wall of the ventricle was remarkably thin.

Dr. G. Langmann thought it was not at all uncommon for persons to live for days, or even weeks, after rupture of the heart. He referred to the case of a shoemaker who, while moving some furniture from one room to another, had been seized with distressing pain over the heart necessitating his going to bed. This pain had gradually subsided, and he had resumed his work. About two weeks later there had been a second severe attack of pain, and physical examination at that time had shown only slight increase in the cardiac dulness, and a feeble and small pulse. The patient had died about four hours later, and the autopsy had revealed not only the fresh rupture in the left ventricle, but an older rupture in the right ventricle. From its appearance and from the history this rupture had evidently occurred two weeks previously. Both ruptures were about midway between the apex and base of the heart. The walls were thin, but there was no marked fatty degeneration.

Three Cases of Tuberculous Peritonitis.—Dr. Leon T. Le Wald reported these cases and presented specimens. The first case was that of a man aged thirty-five years, who had presented at autopsy a tuberculosis of the seminal vesicles and of the epididymis on the left side. The tuberculous process had apparently started in the left epididymis and spread to the prostate. On opening the peritoneal cavity a small quantity of dark fluid had been found, and the peritoneum had been generally studded with tubercles of large size. Miliary tubercles were scattered over the peritoneum covering the intestine, and they were particularly abundant on the under surface of the diaphragm. There was also a rather recent miliary tuberculosis of the lungs. The oldest-looking lesions were in the region of the prostate and the seminal vesicles, though it was not at all unlikely that some small focus in the lung might have been the original process, but the peritoneal tuberculosis was secondary to the genital tuberculosis. The second case was that of a man aged fifty years, who had been treated for cirrhosis of the liver in the Roosevelt Hospital last December. He had been operated on with the idea of determining whether he had a tuberculous peritonitis or an accumulation of fluid entirely the result of the disease in the liver. The operation had revealed nothing more than the cirrhosis of the liver. On March 31st the man's abdomen had been tapped, and fluid removed, and this had failed to show any tubercle bacilli present. On April 4th he had died, and the autopsy had shown a well-marked tuberculous peritonitis. The lungs showed a chronic tuberculosis. The third case was that of a man aged thirty-five years, who had been suffering from alcoholism and cirrhosis of the liver. The autopsy showed a miliary tuberculosis of the peritoneum. A careful search had failed to show any other tuberculous process in the body, so that the case was considered to be one of primary tuberculosis of the peritoneum associated with a marked cirrhosis of the liver. While primary tuberculosis of the peritoneum was quite rare, it was somewhat less so when associated with cirrhosis of the liver, as shown by statistics published by Osler. Ziegler mentioned the occurrence of primary peritoneal tuberculosis, although the manner of its occurrence was not understood.

A Case of Addison's Disease.— Dr. Le Wald also presened specimens from a case of Addison's disease occurring in a woman fifty years of age. The case was typical, so far as the bronzing of the skin was concerned. The skin of the face and neck was of a very dark bronze, and the skin on the hands, wrist, and forearms of a somewhat lighter tint. The body was emaciated. The bronchial glands were markedly enlarged and pigmented. The heart was small and showed brown atrophy. The coronary arteries showed very slight arteriosclerosis. There were old adhesions about the stomach, liver, and spleen. In the large intestine were some cicatricial areas in the mucous membrane, apparently the result of some old ulcers. There were also a few lymphatic nodes which were apparently tuberculous. The right suprarenal was of about twice the normal size, and was adherent to the under surface of the liver. On section, it had been found to be almost entirely replaced by caseous masses. The left suprarenal was surrounded by a mass of adhesions, which bound it to the pancreas. A small abscess had formed between the pancreas and the suprarenal gland. Its contents were cheesy, and the suprarenal gland itself was largely replaced by cheesy nodules. Sections were exhibited under the microscope.

Dr. Carlin Philips asked, in the case of supposed primary tuberculous peritonitis, whether the small nodules contained tubercle bacilli or not. About four or five years ago Wagner described a form of fibroid peritonitis occurring in cases of cirrhosis of the liver which at times resembled in the gross appearance miliary tuberculosis. This condition was termed pseudo-tuberculous peritonitis.

Dr. Le Wald replied that one of the sections exhibited under the microscope showed typical tubercles, and he also had a specimen showing stained tubercle bacilli.

A Case of Papilloma of the Ovary with Secondary Deposits in the Peritoneum.—Dr. G. Langmann said that the president had exhibited at the last meeting one feature of the interesting specimen that he was about to present. The specimen had been taken from a woman seventy-three years old. He had known her for several years, and knew that she had a large tumor on the right side, apparently ovarian. Last October he had been called to see her because of a considerable enlargement of the abdomen. Inquiry showed that she had had a severe fall last summer, and that since that time her health had failed, and the abdomen had been increasing in size. When first seen the size of the abdomen had precluded thorough

examination of the abdominal organs. There was a very large, smooth tumor in the abdomen having a hard, blunt border running from side to side. On November 8th, the abdomen was tapped, and about five litres of clear, amber-colored fluid evacuated. Examination after the tapping showed one tumor about the size of a man's head on the right, and another about the size of a fist on the left side. Percussion showed that regular vesicular resonance ran into the tympanitic resonance of the colon. No trace of the liver could be found by percussion. A second tapping had been required in a short time, and bloody fluid had been removed at this operation. Shortly after the third tapping she died. The autopsy revealed an immense ovarian tumor on the right side, and a smaller one on the left side. The liver had not been visible on opening the abdomen. All of the ileum and the omentum were matted together. The vesical and parietal peritoneum was covered with small nodules, as was also part of the surface of the ovarian cyst. The ovarian tumor was a papillary cystadenoma, and some of the cysts were already suppurating. Microscopical examination of the nodules by Dr. Hodenpyl had revealed nothing but ordinary papilloma. When these cysts broke and scattered their contents over the peritoneum nodules developed from direct implantation, so that the result was practically like that of a malignant growth. The fall that this woman had experienced had probably caused a rupture of some of the cysts, and in this way he explained the decline in her health. The autopsy also showed numerous stenoses in the colon, probably as a result of long-continued pressure. They were interesting because of the absence of symptoms pointing to such a condition. The numerous diverticula along the colon had been exhibited by Dr. Hodenpyl at the last meeting of the society.

Dr. Philips stated that in the summer of 1896 Ziegler, of Freiburg, presented to his advanced class in pathology a similar tumor which histologically was a papilliferous cystadenoma of the ovary. He considered the tumor of very great importance, as it was histologically benign but clinically malignant and capable of metastasis.

Dr. Hodenpyl objected to looking upon the case just reported as a malignant growth. It was primarily a connective-tissue tumor, and therefore he would classify it as a benign tumor.

Dr. Langmann replied that one might make a distinction between clinical malignancy and microscopical malignancy. He thought no one would be justified in recommending the early removal of such a cyst because of the possibility of just such an accident as had occurred in this case.

A Demonstration of Nucleic Acid Extracted from Bacillus Tuberculosis.—Dr. P. A. Levene made this demonstration. The products exhibited had been procured from cultures made on synthetic media, *i.e.*, such as were composed of mineral salts and were free from proteid material. The speaker said that all of the nuclear compounds were composed of nucleic acid. Until recently it had been known only that they contained phosphoric acid, and that some of them contained xanthin bases. Only very recently had different nucleic compounds been recognized. It was natural to expect that cells producing diseases would probably store up this power of producing disease in the nuclei, and probably in the nucleic acid. Nucleic acid was more active than the nuclear compound itself. Last year he had presented a paper on the chemistry of the tubercle bacillus, and it was only since then that he had succeeded in devising a method which would enable him to obtain nucleic acid from any cell or tissue whatever. In the tubercle bacillus one found a free nucleic acid, and the nucleic acid in combination with proteid material. He exhibited two samples, one a copper salt obtained from the free acid, and the other procured from the combined nuclein. The acidity in the growth was due partly to the nucleic acid. This could be demonstrated by the fact that nucleic acid had the property of precipitating any proteid, as for instance peptone. The precipitation with peptone was demonstrated. It had occurred to him that this nucleic acid might be the cause of certain necrotic processes taking place around the bacilli.

On the Property of Precipitating Albumin Exhibited by Some Pathogenic Bacteria.—Dr. E. Libman said that he had been surprised to find that nearly all pathogenic bacteria he had tested could precipitate serum-albumin and egg-albumin in the presence of sugar. The result depended largely upon the amount of acid formed. This reaction occurred if only 0.1 per cent. of glucose was present, and this percentage was present in the blood normally. Pneumococci did not precipitate albumin at all. These facts might possibly be of interest in explaining some lesions, especially in diabetics. This study opened up interesting possibilities in connection with acid toxæmiæ in the human body. Dr. Bookman had examined these tubes for him, and had reported that there was no doubt about the precipitate being albumin.

Dr. P. A. Levene thought the reaction was due to the presence of free nucleic acid.

Dr. Libman said that if the acid was nucleic acid, he thought it should act even though sugar was not present.

On the Influence on Normal Animals of Blood from Animals Deprived of their Adrenals.—Dr. I. Levin made some remarks on this subject, and exhibited blood-pressure tracings. These tracings had been made to illustrate the influence on the blood pressure of injecting into a normal animal the defibrinated blood from an animal deprived of its adrenals five hours previously. The tracings showed a marked rise of blood pressure lasting for a considerable time. As a control, tracings were shown of the blood pressure of an animal who had received an injection of defibrinated blood from a normal animal. It showed that there was scarcely any perceptible rise of blood pressure following this injection. These tracings showed that the first injections resulted in a toxic condition. He thought the absence of the tonic action of the adrenals on the muscular and circulatory system was not sufficient to explain that fatal result of the extirpation of these glands.

Dr. Langmann said that some experiments had been made with the suprarenal extract in connection with snake poisoning. Guinea-pigs were particularly susceptible to snake poison, and these animals had almost no adrenal tissue. Suprarenal extract obtained from sheep or oxen was injected into the guinea-pig poisoned with snake poison. These animals showed a much greater resistance to the snake poison. Experiment had shown that only the suprarenals possessed this power. It might be that the effect of the suprarenal extract on the heart and blood pressure was in itself sufficient to account for this increased resistance in the animal without supposing that the product of the adrenals was an antitoxin.

Dr. P. A. Levene said that from the suprarenal a substance had been obtained which produced a tremendous rise of blood pressure. If one accepted the theory of internal secretions, then by removing the gland the substance causing this increase of blood pressure was removed, and the blood of the animal should not contain the substance which caused the rise of blood pressure. This was very different from what had been just described in the experiment of Dr. I. Levin.

On a Method of Photographing Slides.—Dr. Buxton exhibited some photographs taken by a method which he thought would obviate the necessity of using drawings.

Endotheliomata.—Dr. F. C. Wood read this paper, and exhibited a patient. This man had had a tumor in the parotid region for about five years. It had grown rapidly only during the past few months. The tumor was adherent to the deep fascia, and was almost cartilaginous. The object of the paper was to show that there was a class of mixed tumors characterized by slow growth for a long time, and then by a more rapid growth and a change in structure coincident with the change to malignancy. These tumors were derived from the endothelium. As the mesoderm and the tissues which it formed, notably the connective tissue, came from the tissues epithelial in character, certain embryologists insisted that all tumors so derived should be called epithelial tumors. Others contended that tumors arising from the endothelial cells of the peritoneum or pleural cavity or the lymph spaces should be known by the name of endotheliomata. Within a year two prominent foreign pathologists had taken opposite positions on this question. The speaker thought it was inadvisable to go back to the earliest stage of development, and that it was better to classify tumors according to their origin from the tissues as found at birth. A number of microscopical specimens were then projected on the screen by means of an electric lantern.

New Instruments.

DILATATION OF THE LACRYMAL PUNCTUM.

By J. R. SHANNON, M.D.,
NEW YORK.

A great many cases of epiphora coming under the care of ophthalmic surgeons are undoubtedly due to a constriction of the lacrymal punctum, and nothing more. This is not a very original piece of information, and yet in the treatment of the condition the causal element seems to be lost sight of frequently, for we find that in many clinics—and I doubt not in the private practice of many ophthalmologists—the appearance of a patient complaining of the familiar symptoms immediately suggests the canaliculus knife and lacrymal probe. Now, the slitting of the canaliculus probably does no great damage—although this is by no means unquestioned—but it is a mutilation, and an absolutely unnecessary one in the cases under discussion, while the use of the probe is often an offence against a perfectly healthy and uncomplaining duct.

Fig. 1.—Dilator.

Fig. 2.—Syringe.

For some years I have relieved the symptoms arising from atresia and constriction of the lacrymal punctum, as well as of the canaliculus, by dilating both with a small steel dilator, and syringing thoroughly with some mild lotions—boric acid, alum, or weak bichloride. Nor is this treatment startlingly new, for we find it or something like it advocated in most text books on ophthalmology—notably, for instance, by Theobald, in his article in Norris and Oliver's System. But it is not practised at all generally, and why it is not is difficult to explain. To particularize briefly for those who may need it: the dilator which I employ is sufficiently pointed to enable it to enter any punctum not absolutely closed, and yet not sharp enough to wound the conjunctival mucous membrane when carefully used. I sit in front of the patient as a rule, though if the patient is restless, or for any reason the manipulation is difficult, I stand behind the head as for passing the lacrymal probe. If the punctum is quite closed, the point of a Graefe knife may be used to facilitate the entrance of the dilator. The dilator is conically shaped for about one inch of its length; and after having opened the punctum by its being held vertically and gently pressed downward, it is shifted to the horizontal and the point passed well along the canaliculus, the lid meanwhile being held on the stretch by the thumb of the left hand, the punctum dilating as it passes up over the expanding instrument.

The syringe is not unlike an ordinary hypodermic as to the barrel, but the tip is of pure silver, easily bent, and with a slightly bulbous end. The object in having the syringe small is that it does not drag the canaliculus, does not hurt the patient, can be managed with one hand while the other steadies the lid, and at the same time is capable of all the force that is necessary and carries quite enough lotion. I sit in front of the patient always when using it, chiefly that I may see for myself whether the fluid passes freely into the nose. I think this is important, because I have become convinced that patients will frequently declare that the fluid has gone through when it has not, in order to avoid further treatment, especially if it is uncomfortable, and, secondly, because it is unpleasant to have boric or alum lotion syringed into a pharynx which does not want it; whereas with the floor of the nose inclined forward this is avoided, and the operator sees at once the result of his treatment.

My only reason for communicating this note is to draw attention to a very simple method of relieving a simple condition—a method which has proved most satisfactory and convenient in my hands. Of course, when there is an obstruction in the duct the probe must be used—but that is another story.

20 West Thirty-fifth Street.

LINGUAL TONSIL SCISSORS.

By J. H. MORRISON, M.D.,
ST. JOHN, N. B., CANADA.

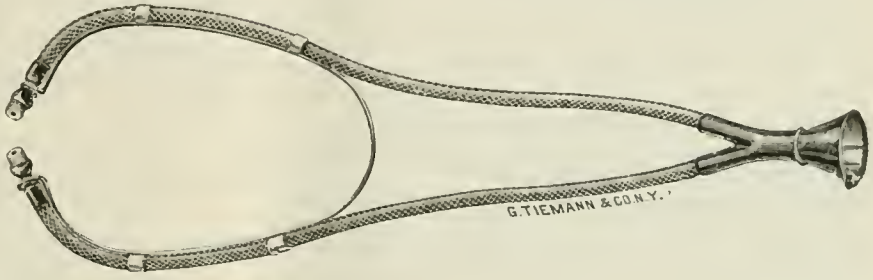
I know of no more awkward predicament into which the throat-surgeon can get himself than, during an attempt to remove a large hypertrophied gland at the base of the tongue with any of the ordinary snares, to find that, after he has engaged the hypertrophied mass in the wire loop, no amount of traction is sufficient to make the wire cut through the tough, fibrous pedicle or base of the tumor. The snare is fast fixed *in situ*, and he can neither complete the excision nor remove the instrument; the patient becomes terrified, gags, chokes, coughs, and often vomits the contents of his stomach into the operator's lap, while every motion of himself or of the operator aggravates his discomfort and increases his alarm.

With the Bosworth snare it is quite impossible to disengage the contracted loop without detaching the proximate ends of the wire from the finger rings, cutting off the twisted portion, and forcibly pulling the instrument away, leaving the wire still fast to the gland. Then one or perhaps two fingers must be inserted into the patient's throat and the wire unhitched from the gland—a difficult and awkward proceeding. If the operator prefers to take up the slack wire and cut the loop in the mouth with a pair of wire-cutters, the cut ends of the loop fly upward and stick into the soft-palate, tonsils, or even up into the naso-pharynx, every motion of the patient's tongue causing him the greatest distress and discomfort. Then the operator must insert his fingers and remove the cut loop, and admit a failure. The chances are that he will never again get a snare into that patient's mouth.

Even with the end-loop snare, in which the loop of wire may be quickly pushed out of the cannula, the greatest difficulty is experienced in removing it from the half-severed pedicle or base.

Generally the fibrous base cannot be cut through by traction made with the fingers; and the nut, wheel, screw, and ratchet attachments are quite useless.

To meet such an emergency, which sooner or later comes to every throat surgeon, I have devised the lingual tonsil scissors shown in the cut. When it is found that the gland cannot be cut through by finger traction upon the snare, the throat mirror is discarded, the scissors are inserted, the points guided by the forefinger of the left hand, and the gland is snipped off with the wire still engaging it. The patient considers it an essential part of the operation, and the whole difficulty is over in a moment. The forefinger should be pushed quickly along the dorsum of the tongue under the cannula until the wire and gland are reached, and the scissors, passed under the finger, cannot fail to reach the exact desired spot. As the parts have been locally anæsthetized, the quiet but rapid introduction of the finger gives the patient no discomfort or concern. With a cool, collected patient, who will continue to pull forward the tip of the tongue, the snare may be passed to the left hand, the tip of the cannula somewhat elevated, bringing the base of the tongue into view, when the contracted pedicle may be quickly severed without the necessity of passing the finger into the mouth.



The instrument, as shown in the cut, is in reality a combination of the Asche septum forceps and the common curved uvula scissors. Beyond the pivot the curve is somewhat less than that of the snare cannula and loop. The shanks are separated and rounded to avoid the possibility of engaging and wounding the dorsum of the tongue. This is an essential point in the construction of the instrument, for the patient is apt to let go his tongue and pull it back into his mouth, where, being arched, it would be sure to get between the cutting blades if they extended back to the pivot. The cutting edges are half an inch long and concave, so that the pedicle cannot escape when they are closed upon it. The tips are blunt and slightly rounded inward toward the cutting line to avoid the possibility of wounding the epiglottis, which might be thrown up against them should the patient gag or cough during their introduction. The handles are long, so that the operator's right hand is quite free and entirely outside of the patient's mouth.

In favorable cases in which the glands are large they may be excised with the scissors without having recourse to the snare at all. In these cases the scissors are, of course, used in conjunction with the throat mirror.

AN IMPROVED STETHOSCOPE.

By MARK I. KNAPP, M.D.,
NEW YORK.

The present stethoscope is an improvement on my first one, a description of which was published in the Medical Record, November 9, 1895, in so far only as the lessened cost is concerned; the quality remaining the same, although the shape and make-up differ.

The principle of this stethoscope is to do away with the humming and buzzing and incidentally to magnify the volume and the quality of the sounds. To effect this I assumed that the annoying sounds came not from within the instrument, but from without, from the atmospheric waves propagated to our ears by the ordinary metallic ear-parts of all other stethoscopes. The solution of the problem was to have a bad sound conductor, rubber, cover a good sound conductor, metal, by which combination I produced an ideal material for a stethoscope.

To lessen the cost of the instrument I have dispensed with its solid metal and rubber covered proximal parts. The present stethoscope then consists of: (1) The distal part, the chest piece, made of metal and covered with rubber; (2) ear-tips, and (3) flexible tubing which intervenes between the chest and the ear-tips. This flexible tubing consists of a spiral wire whose individual rings are so closely apposed to one another as practically to form a metal tube; this is covered with soft-rubber tubing and then spun over with silk. The ends of the ear-tips have soft-rubber covers whose object it is to prevent painful pressure. To give this stethoscope firmness and springiness, a nickel-plated steel spring wire, of sufficient length and breadth to allow the head to move freely, runs from ear-tip to ear-tip; two nickel-plated rings, a quarter of an inch wide and three inches apart, are soldered on to the spring wire about three inches from its ends; the purpose of this is to hold the flexible tubing and give the proper shape to the instrument.

The excellence of this instrument as to its quality in doing away with the buzzing and humming sounds peculiar to all stethoscopes, at the same time increasing the power of the instrument, cannot fail to recommend it to the medical profession.

Elbow-Joint Fractures, especially the intercondyloid in children, should not be treated by too early nor too forcible passive motion.

Medical Items.

Prehistoric Bacteria.—Owing to the ephemeral nature and to the exceedingly small size of bacteria, it would seem wellnigh impossible to study the minute forms which assuredly must have existed ages ago. Two French investigators, B. Renault and C. E. Bertrand, have, however, microscopically examined several varieties of anthracite coal and partially carbonized wood, and believe they have discovered petrified bacilli. Renault has even designated several of his species by name (micrococcus carbo, bacillus carbo, bacillus colletus). He advances the theory that these bacteria have effected the transformation of wood cellulose into coal, a theory which is decidedly opposed to our conception of the carbonization of wood. Bacteria, according to Renault, would therefore be most powerful factors in the geological development of the world.—*Scientific American.*

The Open-Air Treatment of Consumption in Southern Brittany.—The open-air marine treatment for consumption has been practised, says an English weekly journal, with success for several years in Southern Brittany. The Pen-Bron Hospital is famous for its cures. It is used mainly by working-people, the cost of maintenance being defrayed by the local authorities by whom they are sent. Its success has led to the creation of a magnificent private institution at La Baule, a few miles away, for well-to-do patients who can afford to pay for treatment. The new hospital, which is built of granite, looks out upon the sea from beautiful grounds, surrounded by evergreen pine forests. It has been fitted out on a luxurious scale, with a special system of drainage. The hydropathic department comprises hot and sea-water baths, seaweed baths, electric brine baths, and hot-air baths, together with vapor, douche, rain, shower, and medicated baths.

Consumption of Alcohol in France.—In France much dread is being expressed at the steadily growing increase in the consumption of alcohol, and a vigorous crusade has been inaugurated against its excessive use. Not only is alcohol prohibited in military canteens but in civil circles. An effort is being made to secure the registration of deaths directly traceable to alcoholism under this head.

Famine in India.—The reports of the Indian famine, says the London *Spectator*, continue to be heartbreaking. The number of persons on the relief works is now five million seven hundred thousand, and the deaths from fever, cholera, and the diseases promoted by starvation will affect the next census. Mr. Klopsch, the American gentleman sent to distribute American subscriptions, draws a horrible picture of the sufferings of children in Guzerat, whose bodies are often eaten by dogs; and in Rajpootana, Kathawar, and indeed the whole Bombay Presidency the mortality is frightful.

Average Ages of Various Groups.—A general summary of the following groups and individuals shows that the average duration of life has been about sixty-eight years and eight months: 46 poets average 66 years, 39 painters and sculptors 66 years, 30 musicians 62 years, 26 novelists 63 years, 40 men of letters 67 years, 22 religious 66 years, 35 women 69 years, 18 philosophers 65 years, 38 historians 65 years, 58 scientists and inventors 72 years, 14 agitators 69 years, 48 commanders 71 years, 112 statesmen 71 years.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended July 14, 1900:

		Cases.	Deaths.
Smallpox—United States.			
District of Columbia, Washington	July 1st to 7th	4	
Florida, Jacksonville	July 1st to 7th	1	
Illinois, Cairo	July 1st to 7th	7

CHORIO-EPITHELIOMA MALIGNUM.

BY B. S. TALMEY, M.D.,

NEW YORK.

THE study of the new growth called chorio-epithelioma malignum has not cast as yet full light upon the pathology of this interesting tumor. It is therefore desirable to put on record all recognized cases. The succinct history of our present case reads as follows:

In the first days of July, 1899, the autopsy of a woman, with the clinical diagnosis "anæmia," was performed in the pathological institute of the University of Zürich. The woman was delivered in April, and had had since her confinement a light bloody uterine discharge. The rough, lacerated, papulous appearance of the surface of the uterine mucosa of the

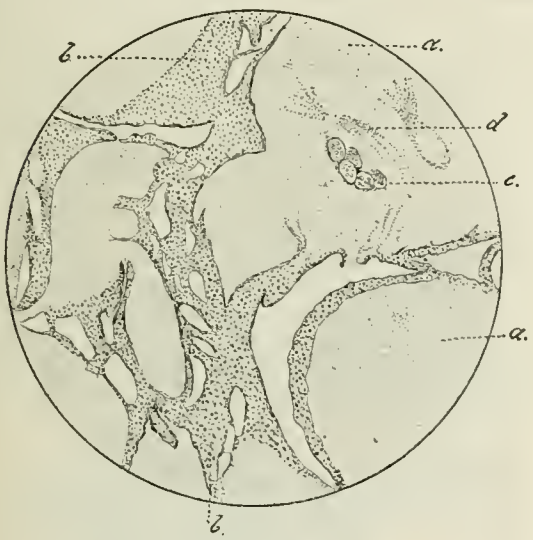

FIG. 1.—*a*, Fibrinous masses; *b*, syncytial masses; *c*, nests of wandering cells of Langhans' layer.

posterior wall, giving the impression of the yet preserved placental site, three months after delivery, caused Professor Ribbert, the director of the institute, to hand me over the uterus for microscopical examination:

The uterus, 13 cm. in length, is somewhat thickened, the posterior wall measuring 2 cm., the anterior 1 cm. The peritoneum is intact. The uterine cavity is somewhat enlarged. The mucosa of the anterior wall gives the aspect of a simple endometritis. At the posterior wall, occupying almost the whole surface of the fundus, a triangular mass is seen growing from the wall and projecting forward into the uterine cavity. The tumor is fungiform in appearance, resting on a broad base (diameter 2½ cm.) in the uterine mucosa, the latter arching over the tumor for some distance. The surface is rough, lacerated, and papulous. The color is reddish-brown. The uterus was fixed in Zenker's fluid, and then slices involving the whole thickness of the uterus were taken from the anterior and posterior walls, hardened in alcohol, cut partly in paraffin, partly in celloidin, stained with hæmatoxylin-eosin and hæmatoxylin-Van Gieson, and mounted in Canada balsam.

FIG. 2.—Portion of Fig. 1, More Magnified to Show the Nests. *n*, Ectodermal cell-nests; *r*, red blood globules.

The bright rose-red stained masses of the tumor can be noticed with the naked eye, occupying half of the uterine wall and reaching almost to the vascular interval between the circular and longitudinal muscular coats. The circular coat has either totally disappeared or is represented by mere remnants. The blood-vessels appear greatly enlarged.

The microscopical examination shows the bulk of the tumor to consist, first, of irregular, branching, multinucleated, trabecular masses, which are distinguished by darkly stained protoplasm. Yet the greater part of the tumor is changed into very dense fibrinous, coagulated masses of irregular outline, enclosing spaces of various shape. At the apex of the tumor the uterine mucosa has entirely disappeared, the fibrinous masses reaching the uterine cavity. At the opposite side the fibrin is closely adherent to the uterine muscles, sending long offshoots into the remnants of the circular layer, upon which it seems to encroach. At some points within the fibrinous masses epitheloid cells, ectodermal cells of Langhans' cellular layer, are seen either single or in small groups of two to three. They are lying in lacunæ of the fibrin. Some of the cells are in a state of degenerative metamorphosis, showing only outlines of cells. Other

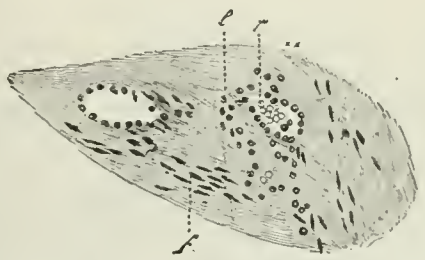

FIG. 3.—Portion of Fig. 2 at *xx* to Show the Residua of the Cellular Elements within the Fibrin. *l*, Lymphocytes; *r*, red blood globules; *f*, spindle-shaped nuclei.

cells are in various states of degeneration. The cells yet normal appear to have only for a time survived this degenerative fate. The fibrin gives us the impression of being the hyaline metamorphosis of these degenerated cells. After careful search some cells

were found lying in larger heaps and adhering together without any intercellular substance. They are surrounded by a circular layer of dense fibrinous tissue,

Fig. 4.—*a*, Fibrinous masses; *b*, syncytial masses; *c*, ectodermal cell; *d*, disintegration of a uterine gland.

giving the appearance of an alveolar sarcomatous tissue; the epithelioid cells are the large granular wandering cells and stain less than those derived from the glandular epithelium. The cell bodies are almost colorless. They are irregularly oval in outline and have usually a single large, well-stained nucleus containing a nucleolus. A few are larger, more granular, and multinucleated. The cells are less individual in the large patches within the alveolus; otherwise there is no difference between them and the single cells scattered within the fibrin. Some cells within the alveoles show mitotic changes. They have not yet entirely lost their proliferating-power.

The large irregular spaces between the fibrinous masses are mostly occupied by the syncytial multinucleated mass of protoplasm without recognizable cell boundaries, as above alluded to. The nuclei are oval, round, or polyhedric in outline; some are spindle-

Fig. 5.—Portion of Fig. 4 at *x*, More Magnified to Show the Nests.

shaped or triangular. The masses lie usually at the margin of the fibrin. The structure is trabecular with processes running off in various directions, making the thick fibrinous trabeculæ appear to be embedded in the syncytial mass. The nuclei of the syncytial masses resemble the connective-tissue nuclei, but are greatly increased in size. The greater part of them resemble enlarged lymphocytes. Some nuclei are surrounded by a light area so as to make a cellular structure appear within the syncytium. The protoplasmatic area appears often homogeneous and hyaline, resembling in color the fibrinous mass.

On both sides of the tumor only a hyperplasia of the mucous membrane is to be noticed, showing an increase of the interglandular connective-tissue cells and a greater widening of the glands. The change of the glands at the edge of the syncytial masses is extremely characteristic. The epithelial cells alter first their cylindrical shape, becoming larger and changing into spherical or cuboidal elements with a central nucleus and a very narrow zone of protoplasm. They soon commence to proliferate, and instead of a single layer several layers are now lining the glandular cavity. In this stage the nucleus is very little enlarged, with a very small, scarcely recognizable margin of protoplasm. The glandular epithelium then breaks down, the cells lying in patches within the glandular cavity, while some of them still adhere to the wall. Finally they detach themselves entirely from the wall and lie irregularly scattered around the former gland's cavity, resembling enlarged lymphocytes. The disintegrated cells are irregular in outline with a round, darkly staining nucleus. Their bodies stain slightly with eosin and appear to be in a stage of hyaline metamorphosis. These aggregations of epithelial cells send out shoots into the syncytial masses. On their way the nuclei lose entirely their narrow marginal protoplasm and fuse finally with the syncytium. I failed to find any decidual cells anywhere.

Fig. 6.—Portion of Fig. 4 at *x.x*, to Show the Disintegration.

The intermuscular connective tissue is somewhat thickened. The uterine blood-vessels in the interval between the remnants of the circular layer and the longitudinal layer are greatly dilated. Especially the media is much thickened, but the looser layer, the adventitia, is also changed. The endothelium seems to be normal. In some transverse sections I was able to recognize syncytial masses within the vessel's lumen.

From the description it is seen that this case agrees in most particulars with those already recorded. It represents the early beginning of a malignant growth. By far the greatest part of the tumor appears to be a pure product of a coagulation as described by Marchand.[1] In his case the small nodule consists also of coagulated products. There can be no doubt that the tumor is a pure case of chorio-epithelioma malignum, The plasmodial syncytial masses were always characterized by three points: (1) absence of cell-outline, (2) deeply staining nuclei, and (3) vacuolation. These three characteristic points are found in our case in the masses surrounding the fibrin. The essen-

tial part of deciduoma, says Pfannenstiel,[2] is the large polymorphic, multinucleated, darkly staining protoplasmatic masses, which were found by all the authors

and which are partly derived from the syncytium. The protoplasmatic masses in our case are also multinucleated and darkly staining. They are partly seen in coherent chains, partly dissolved into single individuals as Freund[3] characterizes them. Freund found also that in the malignant chorionic growths the syncytial proliferation does not always penetrate the tissue in form of coherent chains, but dissolves into single individuals, which are lying either isolated or in heaps near each other. Besides numerous large multiform cells, the syncytial wandering cells are also found in our case dispersed through the fibrinous tissue and at some points in larger aggregations. There is therefore no doubt that the tumor is composed of the two elements which form the normal epithelium of the chorionic villi, of syncytium and ectodermal cells. The tumor is further characterized as malignant by its completely destroying the muscular fascicles to the entire depth to which it invades the uterine wall.

A few words will now suffice about the strange presence of the enormous fibrinous masses. Marchand considers this coagulation to be the first stage in the formation of the tumor. I, on the other hand, am inclined to think it is the last stage in the process. Hyaline metamorphosis is generally a sign of degeneration and not of proliferation. I perfectly agree, therefore, with Gottschalk,[4] who found that the farther the villi penetrate the wall of the uterus, the more the superficial parts are separated from their nutritive soil and suffer a speedy necrosis. This necrosis may easily assume larger dimensions. Even the whole nodule can be affected by it. In our case the hyaline degeneration is also considerably more advanced in the deeper than in the peripheral portions of the tumor. This necrosis would thus represent nature's attempt at healing, as the formation of colloid in carcinoma colloids. She fails, because the yet living syncytial masses continue to proliferate, destroying everything in their advance.

As to the origin of the fibrin, it seemed to me that the large ectodermal cells stand mainly in close relation to the formation of the fibrin. I will not deny the possible participation of the syncytial masses in this formation. I have often found a hyaline degeneration in the round granular cells, with obvious division into nucleus and surrounding protoplasm derived from the glandular uterine epithelium. The narrow margin of protoplasm becomes more homogeneous, appearing hyaline and glistening and greatly resembling in color the fibrinous masses. Minot's[5] observations show also conclusively that the canalicular fibrin arises through a degenerative metamorphosis of the epithelium, which begins in the outer layer and may invade the inner layer, the cell layer of Langhans. In the large patches the cells are less individual, owing to the spread of the process of degeneration into the layer. But the presence of the polyhedral, large granular wandering cells irregularly spread through the fibrinous masses makes the view more acceptable, that the fibrin is mainly the product of the degenerated cells of Langhans' layer, and the outlines of cells that are still plainly recognizable, show the various degrees of the process of degeneration (compare Fig. 8).

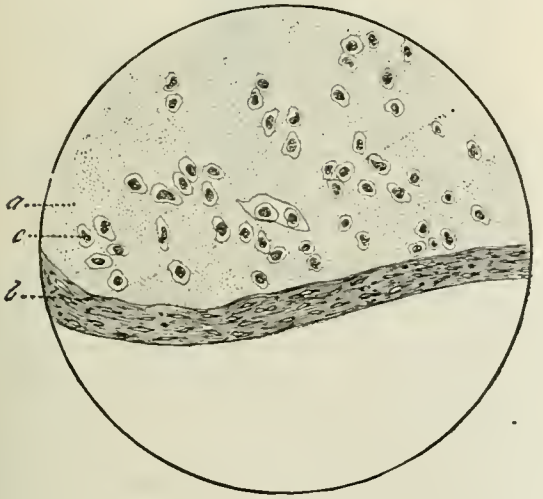

Fig. 8.—Showing the Degenerative Metamorphosis of Langhans' Cells into Fibrin. *a*, Fibrin; *b*, syncytium; *c*, ectodermal cells.

The disintegration of the glandular epithelium and its change into syncytial masses, as seen in our case in spots near the tumor, are especially instructive. The epithelium is found in various stages of conversion into syncytium. It can be noted how the cylindrical cells become cuboidal and oval in shape. They soon break down. Each cell is cleft from its fellows, and some of them, loosened from the wall, lie free in the glandular cavity. Finally they fuse together and dissolve in the syncytial masses. I have therefore no doubt to attribute the origin of the syncytium to the glandular uterine epithelium. Turner[6] assigns the deep layer to the chorion as its true and only epithelium and the outer layer to the uterus. But after accepting the outer layer as maternal the question as to its origin still remained. Marchand[7] is of the opinion that the syncytium can be traced back to the changed uterine epithelium or to the outer epithelial layer of the chorionic villi that is derived from the former. Kossman[8] says: There cannot now be any doubt that the syncytium is nothing else than the changed uterine epithelium, changed by an obliteration of the cell-boundaries. Selenka[9] also found that the villi of the chorion invade the uterine glands and in further advancing receive the flattened glandular epithelium as a second layer for their investment. In our case I failed to recognize true chorionic villi anywhere, yet the glandular epithelium continues to change into syncytium. This atypical formation shows the malignancy of the tumor; the glands continue to furnish syncytium as an investment for villi that are no more in existence.

HYPOSPADIAS OPERATED ON BY BECK'S METHOD.[1]

By FERD. C. VALENTINE, M.D.,

PROFESSOR OF GENITO-URINARY DISEASES, NEW YORK SCHOOL OF CLINICAL MEDICINE; GENITO-URINARY SURGEON, WEST SIDE GERMAN DISPENSARY; GENITO-URINARY CONSULTANT TO THE METROPOLITAN HOSPITAL AND DISPENSARY; TO THE UNITED HEBREW CHARITIES, ETC.

THE hypospadias in this case was penile; the urethra opened half an inch below the glans. The glans

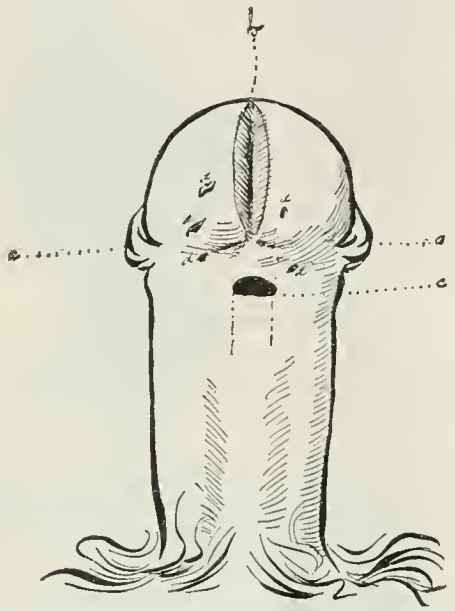

FIG. 1.—Front View. *a*, *a*, Prepuce partly encircling the glans; *b*, sulcus taking the place of the fossa navicularis; *c*, abnormal urethral orifice; *d*, *d*, *d*, *d*, openings of para-urethral fistulæ.

itself appeared normal, except when its lower halves were separated; this then revealed them to be ununited, a deep, wide sulcus occupying the place of the fossa navicularis (Fig. 1). Five para-urethral fistulæ opened irregularly about the urethral opening and the glans.

On inserting a sound into the urethra, the relations became more evident and the glans seemed almost an

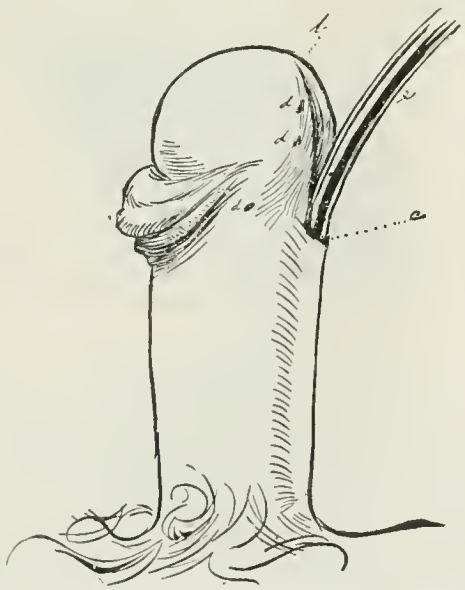

FIG. 2.—Lateral View. *a*, Prepuce forming a ruff about the posterior part of the penis; *b*, sulcus in place of the fossa navicularis; *c*, abnormal urethral orifice; *d*, *d*, *d*, para-urethral fistulæ; *e*, sound inserted into the abnormal urethral orifice.

independent attachment to the penis (Fig. 2). As the treatment of this case demonstrates the typical Beck operation for hypospadias, it will be well to recite each step of the procedure as it was performed:

An incision was carried from the centre of the abnormal urethral opening, through the skin, to the posterior third of the pendulous portion. At the upper end of this incision another was made through the skin, encircling the lower third of the neck of the penis, immediately below the coronary sulcus. The skin-flaps so obtained were dissected back to expose the lower third of the penis. Then the urethra, together with its corpus cavernosum, was dissected from its bed between the corpora cavernosa penis (Fig. 3). A narrow, straight bistoury was then thrust through the glans (Fig. 4) from below upward and well behind the sulcus which normally would have been the fossa, making a new meatus about a quarter of an inch behind the topmost angle of this sulcus. The point of emergence of the knife was enlarged by turning it to the right and the left, making an incision at each side.

After the knife was withdrawn, a long, narrow forceps was passed from above through the channel and the urethra grasped (Fig. 5).

Owing to the longitudinal extensibility of the urethra, first described by Beck, it was rather easy to

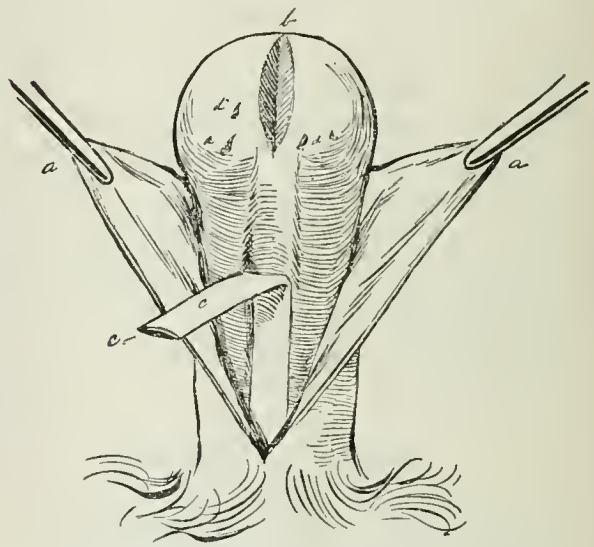

FIG. 3.—First, Second, and Third Steps of the Beck Operation for Hypospadias. *a*, *a*, Skin flaps dissected from the lower surface of the penis; *b*, sulcus in the glans; *c*, *c*, urethra dissected out; *d*, *d*, *d*, para-urethral fistulæ, disregarded during the operation.

NOTE: The skin flaps (*a*, *a*) appear in this illustration somewhat more widely dissected from the penis than they were in reality.

draw the freed end of the urethra through the channel perforating the glans and to attach its opening by means of four sutures to the new meatus. In so doing the glans was somewhat crushed forward, thus obliterating the deep sulcus which had occupied the place of the fossa navicularis. The para-urethral fistulæ were disregarded during the operating.

After attaching the end of the urethra, as before described, the flaps beneath the glans were sutured into their former position.

On the third night after the operation, the patient had a seminal emission, during which one of the stitches at the meatus was torn out of the tissues. Another was substituted for it and the healing thereafter was eventless.

The site of the incisions was at first infiltrated, as would naturally be expected. The consequence was that erections were incurvated at an angle formed by the glans and the penis. This infiltration gradually yielded to dilatations of the anterior third of the urethra, so that now, two months after operation, the patient reports his erections as entirely painless and with not enough incurvation remaining to prevent intromission in coitus (Fig. 6).

[1] Demonstrated before the Genito-Urinary Section, New York Academy of Medicine, April 18, 1900.

The para-urethral fistulæ, which were disregarded during the operation, closed spontaneously. No vestige of them is now visible. The mental depression of the patient, due to the continued consciousness of deformity, has also disappeared.

In attributing this ingenious operation to Carl Beck, of New York, I am not actuated solely by patriotism. The special facilities that were so kindly afforded me for study and observation by the great men of Germany, France, and England would preclude my being ungrateful, by insisting otherwise than that science has no country. Moreover, Beck needs no champion to advocate his cause. But I may be allowed to avail myself of this occasion to protest against the all too prevalent tendency that exists to "originate" an operation, a method, or an instrument which another has fully described before. In such secondary "discoveries," the real originator is most egregiously ignored. Sometimes the new "originator," who was present at the first demonstration, or studied the first publication of the one who devised the novelty, adds to it a useless or deleterious suppendage; it would be charity to

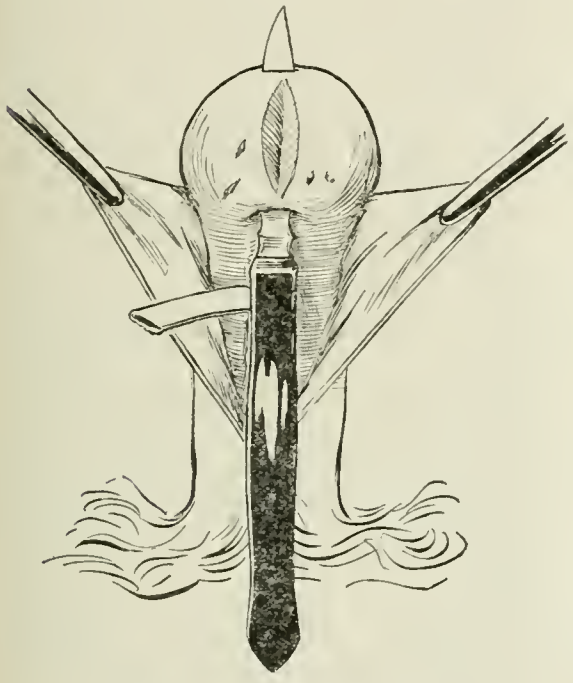

Fig. 4.—Formation of a New Channel through the Glans.

aver that he did so through a capricious memory, which caused him to forget that the genuine work was done by his predecessor. Carl Beck, of New York, is among those made to suffer by such treatment, as literature shows. On October 4, 1897, he demonstrated his operation for hypospadias before the Deutsche medicinische Gesellschaft der Stadt New York; this he described in the *New Yorker medicinische Monatsschrift* for November, 1897. In the *New York Medical Journal* for January 29, 1898, he detailed the operation, and in doing so he distinctly specified its essential features, among them "dissecting the urethra from its bed and extending it to do the service of a new canal." von Hacker ten months later (*Beiträge zur klinischen Chirurgie*, August, 1898) announced the identical operation as his own. Another author, Brevcer, performed the same feat (*Centralblatt für Chirurgie*, No. 29, 1898), but he afterward gracefully conceded Beck's priority. I hold, therefore, that I am fully justified in designating as Beck's the operation done in this case. If Beck's priority needs further proof, it will be found on pages 157 and 158 of the *Beiträge zur klinischen Chirurgie* (April, 1900) containing the reports of Heidelberg Surgical Clinic for 1898. In this report 3 cases of hypospadias operated upon by Beck's method are reported.

After presenting the case, a number of fellows of the Academy, in discussing it, warmly congratulated

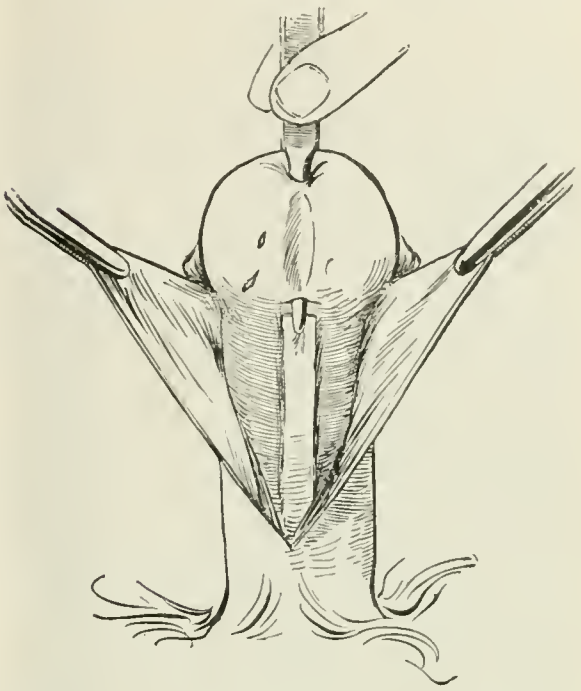

Fig. 5.—Drawing the Urethra through the New Channel.

me on the results. I deemed it my duty to say, and take occasion now to repeat, that all the congratulations I received belong to Dr. Carl Beck, who not only devised the method but rendered the valuable encour-

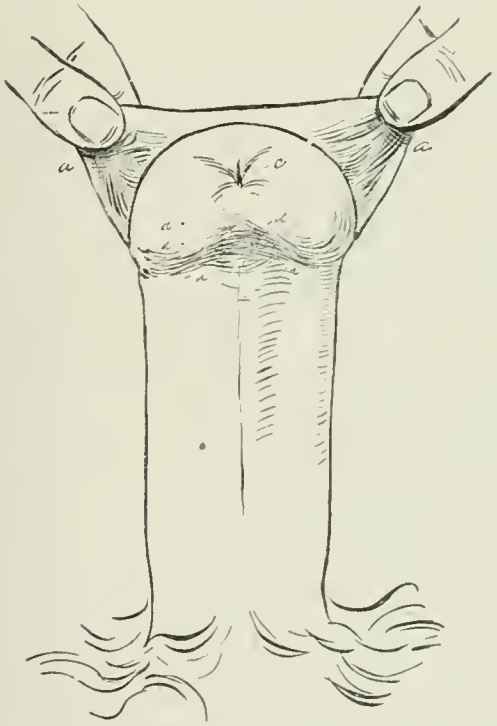

Fig. 6.—Two Months After Operation. The penis is raised by the defective prepuce (*a*, *a*), which is stretched so as thoroughly to expose the organ; *c*, new meatus; *d*, *d*, *d*, *d*, *d*, sites of the former para-urethral fistulæ.

agement of his presence and personal aid in the operations.

I desire publicly to thank my patient, Mr. C. S——, for coming before the section.

For Tremor in paralysis agitans, hyoscine hydrobromate, gr. $\frac{1}{200}$, twice daily.

THE PERITONEUM—ANATOMY, PHYSIOLOGY, AND PATHOLOGY.

By BYRON ROBINSON, B.S., M.D.,

CHICAGO,

PROFESSOR IN THE CHICAGO POST-GRADUATE SCHOOL OF GYNÆCOLOGY AND ABDOMINAL SURGERY.

Anatomy.—The peritoneum is a lymph sac whose walls line the abdominal cavity. The peritoneum proper begins and perfects itself in the fish. From fish to man the peritoneum is the same structure: nothing added, nothing subtracted, only modified. Peritoneal pores (pori peritoneales) begin in the fish and exist in the man as the ostia abdominalia at the ends of the oviducts. It appears that the abdominal cavity or cœlom, *i.e.*, the space between the ectoderm and the entoderm, was once filled with mesoderm and that it atrophied or partially disappeared, leaving the viscera covered with peritoneum projecting into it.

The essential structure of the peritoneum is an exceedingly thin membrane, composed of endothelial cells so arranged with their edges in contact that the membrane is continuous or uninterrupted. The endothelial cell is a connective-tissue cell flattened by pressure or stretching in the embryo. Lying between the endothelial cells are interendothelial spaces. At the junction of several endothelial cells there exists an aperture (mouth) called a stoma verum, which is lined with granular polyhedral nucleated cells. Located in the interendothelial spaces are the stomata spuria. The stomata open into the subperitoneal lymph channels. Silver nitrate one-fourth per cent. applied to fresh peritoneum brings to view microscopically the outlines of the endothelial cells, stomata vera et spuria, and the interendothelial spaces.

The four elements of the peritoneum—(*a*) endothelial cell, (*b*) interendothelial spaces, (*c*) stomata vera, (*d*) stomata spuria—constitute the structure peculiar to the peritoneum. The subperitoneal tissue is simply mesodermic tissue. The anatomical use of the peritoneum is to anchor and limit the motion of the viscera; to produce maximum motion with minimum friction. The peritoneum is a joint of vast interest and dimensions. It is endowed with wonderful elasticity and is very mobile on its base. The internal peritoneum surface is smooth, shiny, moist, and slippery from its secretions. It is a closed sac except in the female. Of special interest in the peritoneum are the mesenteries, which consist of a peritoneal (endothelial) mesentery (temporary or permanent), and a mesodermic mesentery (permanent). The utility of the mesentery is as a neuro-vascular visceral pedicle, and to limit the motion and position of viscera.

Physiology.—The physiology of the peritoneum is its utility in the animal economy. It is the most important serous membrane in the body, from its relation to and influence over numerous and different viscera, and also its life-protecting capacity. Experimentation alone can demonstrate its use. It is a joint in all its functions. It absorbs and secretes fluid. Fluids poured into the living peritoneal cavity disappear at the rate of (in the dog) ten per cent. of the body weight in an hour (and at the rate of five per cent. a few hours after death).

To discover the paths of fluid exit from the peritoneum, pour in fluid containing particles of Berlin blue, which will be found to be directed chiefly toward the diaphragm and through the lymph channels. The particles of Berlin blue will be found passing through the chief stomata vera, aided by thousands of leucocytes which swarm out of the peritoneal mouths, seizing the Berlin-blue particles and hastening onward with them into the subperitoneal lymph channels.

From my own numerous experiments and those of others, it appears we are warranted in the following physiological conclusions:

1. The primary path by which fluids pass from the peritoneum into the circulation is by the way of the lymphatics. The secondary path is the blood-vessels. Hamberger, with some others, asserts that the primary path is by the way of the blood-vessels.

2. A stream of fluid exists in the peritoneum directed toward the diaphragm.

3. The anatomical structure, physiological function (respiration), of the diaphragm enables it to act like a suction or force pump.

4. In five minutes after injection of a solution holding Berlin blue in suspension into the abdomen, the colored granules may be found in the sub-diaphragmatic lymph bed and intra-thoracic glands.

5. So far as my experiments extend, the diaphragm is the primary locality of peritoneal absorption of solid granules. Others assert that the rootlets of the portal vein also absorb solids, but I have not been able to confirm it.

6. The vast function of absorption performed by the diaphragm, and the very small part taken in this process by other portions of the peritoneum, account for the non-fatality in cases in which there is a purulent condition found at the oviductal ends and about the appendix, and when there is a ruptured gall bladder, which is circumscribed and confined by the ligamentum hepato-colicum. The virulent microbes or their products are not absorbed, but circumscribed.

7. On account of vigorous absorptive powers, the nearer peritonitis approaches the diaphragm the more dangerous it is to life.

8. The stomata vera are the most numerous and constant of the diaphragmatic serosa. They are the mouths of the vast lymph bed located in the diaphragm.

9. When foreign bodies (microbes or colored granules) enter the peritoneum the leucocytes swarm out (*a*) to digest the invader, (*b*) to surround or imprison the microbe, or (*c*) to sterilize the germ.

10. It appears to be the leucocyte which carries the colored granules from the peritoneal cavity through the stomata vera into the sub-peritoneal diaphragmatic lymphatics.

11. The normal peritoneum is automatic in regulating the quantity of fluids contained. Normally it will absorb all excessive fluid; but in abnormal conditions it may only add to the fluid injected.

12. If potassium ferrocyanide is injected into the peritoneal cavity it will appear in the urine much sooner (about twenty minutes) if the thoracic duct is not ligated. Ligation of the thoracic duct retards its appearance in the urine. Hence, with open lymphatics the ferrocyanide appears in the urine much more rapidly.

13. The diaphragm absorbs fluid perhaps by imbibition. Imbibition is molecular when a mass of tissue absorbs the fluid, and capillary when it passes through the pores of the vessels.

The forces which are said to produce peritoneal absorption of fluids may be enumerated as follows: (*a*) Vital cell forces, (*b*) stomata, (*c*) imbibition, (*d*) infiltration, (*e*) intra-abdominal pressure (mechanical), (*f*) osmosis.

The leucocytes act as a body-guard to the peritoneum. At a moment's notice (irritation), the army of leucocytes emerge to protect the peritoneum against the invasion, viz., by digestion, imprisonment, transportation, or sterilization of the foreign body, be it vegetable germ or inorganic particle.

The peritoneum has a limited power to resist septic germs. At present we have no standard by which the power may be measured. The power to resist septic germs is slightly different in animals. The perito-

neum of the pig, rabbit, and cow resist considerable quantities of septic organisms. The mare's peritoneum is so sensitive to septic germs that laparotomy on her is almost always fatal. The dog and man are about equal in their power to resist peritoneal invasions of pathogenic germs. Some, however, claim that the peritoneum of a dog resists more than that of man.

The rapid fluid absorption by the peritoneum argues against irrigation in laparotomy, from the fact that by irrigation the germs would become widely and rapidly distributed.

Pathology.—That disease of the peritoneum is also a matter of experimentation was demonstrated in the rapid development of the science of abdominal surgery. Peritonitis saves life, while sepsis kills. Peritonitis is a life-saving process: it builds barriers against the invading host, while absorption overwhelms the system with infective products. Peritoneal exudates circumscribe microbes; imprison and sterilize them. The diagnosis of peritonitis should be more cultivated. The temperature is often of the least value in the most critical cases. The pulse is the most reliable. Tympanites, abdominal muscular rigidity, tenderness on pressure, and the facies peritonei tell their own tale. It must be definitely understood that patients suffering from septic peritonitis are in a state of toxæmia, which clinically resembles profound shock. The nervous system is profoundly impressed with sepsis. Such patients bear anæsthesia very badly, hence the operation for all septic cases of peritonitis which are surgical should be done under very little anæsthesia, supported by hot rectal injections, or hypodermic doses of strychnine and whiskey in the rectum. The pulse must be watched every moment, as collapse may occur at any time. With definite diagnosis, a median abdominal incision should be made. During operation the intestines must be thoroughly protected and wrapped in moist, warm towels. The examination of the intestines should be performed systematically. It should be the rule first to strike for the landmarks, pelvic, appendicular, and gall-bladder region, and if the lesion is not found, to continue systematic examination until it is found. Irrigation should not be employed: it only distributes germs. A rubber tube enclosed in strips of gauze makes the best drain.

After the operation, mild chloride in one-grain doses every hour, with a half to one teaspoonful of sulphate of magnesia hourly, until five grains of mild chloride and six drachms to two ounces of salts are taken, is a useful course to follow. This revives intestinal peristalsis, starts the secretions, and affords drainage from the mucosa. One-sixtieth of a grain of sulphate of strychnine every hour aids peristalsis. All the whiskey a septic patient can bear is good treatment.

To observe the phenomena of peritonitis the following experiment speaks volumes: I injected the peritoneum of a turtle with an ounce of water holding Berlin blue in fine suspension. Four or five weeks later the turtle (four pounds) died of peritonitis. The autopsy showed œdematous and intensely vascular peritoneum. In short, the interpreted results were the following: The fine particles of Berlin blue were distributed in the lymphatic vessels of the peritoneum. They collected especially along the numerous pigment cells which aid to make the walls of the lymph vessels. Large masses of exudates could be seen over the endothelial surface. The endothelia were desquamated, leaving pits on the surface. Numerous leucocytes were to be seen emerging through the stomata and interendothelial spaces. They attack all foreign bodies and surround, imprison, sterilize, or digest them. Hemorrhagic peritonitis existed in localities, *i.e.*, thousands of red blood corpuscles were emerging on the endothelial surface from endothelial lesions.

The signification of this terribly destructive process is: (*a*) the endothelial surface is an infective atrium; (*b*) the endothelial or peritoneal surface is trying to defend itself by (1) calling out the body-guard, the army of white corpuscles, the leucocytes, who are swarming on the surface. They emerge through the stomata and interendothelial spaces. These leucocytes may be seen partially through and fixed in the stomata or interendothelial spaces. They are merciless on intruders, seizing and surrounding them, imprisoning, sterilizing, isolating, and even devouring them. (2) The exudate pours out vast quantities in response to the irritant (microbe or its product). The exudate builds forts or barriers and checks invasion by mechanical means. The battle is never a drawn one: it must be lost or won. It is to kill or to be killed; the microbes or the leucocytes must be victorious. If the battle between the leucocytes and microbes lasts long, the heaps of slain leucocytes or microbes attest the fierce combat for life.

The hemorrhagic peritoneum reports partial or complete victory of the microbe or its products (chemical). The endothelia have become desquamated, loosened in their pitted bed, producing a lesion in the peritoneum, out of which ooze thousands of red corpuscles; the enemy is conquering the territory. The process known as peritonitis—a life-saving process—has yielded to infection, which kills.

The leucocytes, the body-guard of the peritoneum, are capable of vast resistance. The leucocytes are an automatic standing army, and whatever calls out the one leucocyte appears to call out a host sufficient for the occasion. The treatment for such a peritoneum is drainage and not irrigation, which would rapidly sweep the pathogenic microbes and their chemical products to distant fields, entirely out of reach of the mobilized army of leucocytes on the original battle-field.

The peritoneum is a lymph sac. It is a serous membrane, similar to the pleura, pericardium, and synovia. If one will imagine the empty abdominal cavity lined with peritoneum, and the viscera gradually growing from the dorsal wall, pushing the peritoneum before them until they fill the cavity, a good view of the peritoneal relations will be obtained. It forms supports to organs by anchoring and holding them in definite relations. The supports are called mesenteries, for intestinal supports; ligaments, for the support of more solid organs; and omenta, connecting the stomach to some other organ.

The peritoneum consists of two diverticula—a lesser and a greater—communicating with each other through the foramen of Winslow. All organs lie outside of the peritoneum. It is a closed sac superimposed on the viscera and tucked between and among visceral folds. In woman an anatomical peculiarity exists, namely, the two openings in the peritoneum for the transmission of ova. The mature egg breaks through the folds of peritoneum which cover the ovary, and the oviduct opens into the peritoneal cavity in order to secure it for carriage to the uterine cavity, so that the ovum really passes through both peritoneal layers to reach the uterus. It is this unique connection of oviduct to serous cavity, this continuation of mucous membrane with serous membrane, that constitutes the peculiar liability of the female to local peritonitis. The pelvic peritoneum is particularly loose. It rests on the pelvic organs in the centre, but on each side it rests on soft, white areolar tissue (the subserosium).

The relations of the peritoneum are much altered after labor. I have found the pelvic peritoneum thicker in women than in men.

The use of the peritoneum is: (*a*) To prevent friction to moving viscera; (*b*) to anchor and support the viscera in proper relations; (*c*) to prevent the invasion

of infection by throwing out barriers of exudates to protect wounded viscera; (*d*) to limit viscera so that they may not become entangled; (*e*) to furnish the viscera with an elastic covering; (*f*) to absorb and secrete fluid.

In the abdominal cavity there exists a great fold of peritoneum, known as the omentum. It acts as the great protector from infectious invasions. It will plug visceral wounds and heal other wounds. It is like a man-of-war which is ready at any time to move to attacked points, wherever infection invades the peritoneal cavity—at the appendix, gall bladder, or oviductal ends, the omentum stands ready to circumscribe the infectious invader. It corrals the enemy of the peritoneum with exudates. It indicates the point of invasion. It is like a moving sentinel whose beat is its whole cœlom.

The peritoneum is liable to inflammation—peritonitis. The infection must generally attack the peritoneum from the inside, for it withstands very much infection and trauma from the outside, without apparent inflammation. The trauma of the psoas muscle on any segment of bowel which lies within its range induces the migration of pathogenic microbes and eventually induces peritonitis. This may be the case with any segment of the bowel which may lie on the psoas. It may be the case also with the appendix, the cæcum, and the lower end of the ileum. There is over seventy-five per cent. of peritonitis in the right iliac fossa due to trauma of the psoas on the bowels. Much appendicitis is due to trauma of the psoas.

One of the chief essentials of peritonitis (after infection) seems to be that the epithelium must be denuded to start the infection, *i.e.*, there must be sufficient trauma to break off the flat serous epithelium in order to give a growing medium for the pathogenic microbes. Pathogenic microbes can, it is true, be injected into a healthy peritoneum without causing peritonitis, but in contact with denuded epithelium these infectious agents give rise to violent peritonitis. Laparotomy is just the process to furnish all the required trauma to denude the delicate epithelium. With the shingles torn off a roof, it will leak; and similarly with the shingles of the flat epithelium torn from the peritoneal surface, it affords ample opportunity for the invasion of pathogenic microbes. Trauma leads the way to peritonitis.

Peritonitis always begins locally. The two sexes seem to suffer from it to about the same extent, though from different causes. Man has much more hernia than woman. Woman has much more pelvic peritonitis, or peritonitis at the ends of the oviducts; but man has four times as much appendicitis from trauma of the psoas. Man has more volvulus, but woman is afflicted much oftener with derangement of the gall bladder.

Local peritonitis arises at the following points: (*a*) at the ends of the oviducts, where infection passes into the peritoneal cavity. This is the most common localization of the affection designated "pelvic peritonitis." The gonococcus prepares the way for all other pathogenic microbes—by trauma.

(*b*) At the hernial openings. This occurs some three or four times as often in man as in woman. The peritonitis arises from irritation or strangulation, trauma of the intestine in the hernial opening, thus allowing the passage of pathogenic microbes through the bowel wall to the peritoneum, inducing local peritonitis.

(*c*) At the appendix. Perforation of the appendix induces local peritonitis by the escape of pathogenic microbes. This form of local peritonitis is four times as frequent in man as in woman. In short, peritonitis in man or boy should be considered as appendicitis until otherwise proven.

(*d*) At the gall bladder. Perforation or migration arises and peritonitis follows. This form is four times as frequent in woman as in man. Over one-third of the autopsies I have made on women above forty-five have shown local peritonitis around the gall bladder.

(*e*) At the pylorus (sphincter) peritonitis chiefly arises from malignant invasion.

(*f*) At the ileo-cæcal valve (sphincter).

(*g*) At the anus (sphincter) peritonitis is not infrequent. It occurs oftener in woman than in man, on account of the more frequent occurrence of stricture in the female rectum, due to gonorrhœa.

(*h*) At the hepatic flexure.

(*i*) At the splenic flexure.

(*j*) The trauma of the psoas muscle induces the migration of pathogenic microbes or their products through the mucosa muscularis, ending in inflammation of the adjacent serosa. Peritonitis in the sigmoid flexure is due chiefly to trauma of the psoas. At the sigmoid flexure the friction of fæces abrades the mucous membrane, thus allowing the pathogenic microbes to pass through the intestinal walls, where they induce peritonitis around the flexure.

(*k*) Peritonitis occurs about the spleen in ninety-five per cent. of cases; due to muscular trauma (diaphragmatic).

(*l*) It occurs in the mesentery on its lower end, due to muscular trauma or aortic trauma.

(*m*) Local peritonitis occurs in the range of action of the pillars of the diaphragm, especially where the duodenum crosses the right crus.

(*n*) It may occur at the flexura duodeno-jejunalis. Observe that local peritonitis occurs about flexures and sphincters of the bowel.

(*o*) At any point where infection may invade the peritoneum, *e.g.*, at any perforation of the alimentary canal, the genital tract, or urinary passages, where infectious matter may pass into some part of the peritoneal cavity.

(*p*) Tuberculous peritonitis is a common disease. It frequently begins at the fimbriated ends of the oviducts. It is chiefly cured by peritoneal incision and drainage.

Generally, abdominal tenderness, muscular rigidity, and abdominal pain mean peritonitis which has started from some infectious focus, as peritonitis is a secondary disease.

The exquisite tenderness found in the distinct locations of large tumors generally indicates local peritonitis. Severe tenderness in parts of the pelvis is generally caused by peritonitis, induced by infectious matter escaping from the oviduct ends. The local peritonitis may be recent and very tender, or old and not acutely tender, but still giving, on all active motion, a dull, sickening, aching sensation from old adhesions. The adhesions may persist and induce these dull pains for many years, especially in child-bearing life, as monthly exacerbations occur.

Satisfactory recoveries after section, when the adhesions have been broken up, show the adhesions were the cause of the protracted pain and illness. The adhesions seem to irritate the nerves by pinching and compressing them, and checking peristalsis. They disturb circulation by congestion or anæmia of the parts, and by drawing viscera out of normal relations. It may be observed that when the visceral peritoneum is involved only, the pain is of a dull character—only the sympathetic nerves are attacked—but when there is parietal peritoneum, the spinal nerves as well as the sympathetic are involved, and the pain assumes an acute, lancinating character. Pain which involves the sympathetic is dull, while that which involves the cerebro-spinal nerves is sharp and lancinating. A patient practically never recovers from general peri-

tonitis. The barriers which check it are the mesenteries. The colon is the benign area of peritonitis. The enteron is the fatal area.

The following forms are recognized in autopsies. However, the classification of peritonitis is unsettled, but traumatic, infectious, or chemical peritonitis is observed in all forms.

(*a*) Progressive fibrinous peritonitis. This is where exudates and adhesions play the rôle. With new exacerbations new exudates arise; so that many centres of septic foci may be circumscribed. Such pent-up collections of pus may be separately opened without communicating with each other or the general peritoneal cavity.

(*b*) Diffuse suppurative peritonitis. Nearly all such cases are rapidly fatal.

(*c*) A so-called dry form of peritonitis. In some two hundred autopsies on dogs, but few cases of dry peritonitis were found, and it is similar in man. The disease slowly progresses over the peritoneum. In the human I saw it a few times only in over five hundred personal autopsies. Practically excluding perforation, peritonitis occurs (*a*) at the longest range of muscular action (trauma), (*b*) at the bowel flexures, (*c*) the sphincters of the tractus intestinalis, and (*d*) at the fimbriated ends of the oviducts.

(*d*) Another form, called intestino-peritoneal septicæmia, exists. It may depend on ptomains or microbes.

Man has relatively the least amount of peritoneum of any animal. The folds of peritoneum are more ample and extensive in all other animals which I have examined, as the horse, dog, pig, coon, cow, monkey, fish, bird, turtle, frog, seal, snake, sheep, etc. The different animals vary in their susceptibility to infection and peritonitis. The horse has a peritoneum so susceptible to infection, and peritonitis with him is so fatal, that equine abdominal surgery is scarcely possible in the present state of surgical knowledge. The dog's peritoneum is comparatively the same in extent and resistance as man's. The pig is not very susceptible to peritonitis. It is well shown in spaying cows that these animals do not possess a peritoneum sensitive to inflammation.

One of the fell destroyers in mammalian life is peritonitis. When a horse becomes attacked with it, he is not expected to recover. But happily in man the majority recover.

Peritonitis ranks as one of the most important surgical conditions, on account of both its frequency and its fatality. The etiology of peritonitis rests on pathogenic microbes or their products (chemical). The various germs most intimately connected with peritonitis are the colon bacillus, streptococcus, staphylococcus, pneumococcus, and gonococcus.

Traumatic peritonitis is nothing more than the establishment of a focus of lessened resistance, with infection.

The most virulent of all pathogenic germs in peritonitis is the streptococcus. The mildest is staphylococcus. If one performs several hundred adult post-mortems, he will find local peritonitis in the pelvis of about eighty per cent. In females, about the sigmoid, eighty per cent.; about the cæco-appendix, seventy per cent.; about the gall bladder forty per cent.; and around the spleen, ninety-five per cent. With partial exception of pelvic peritonitis, the other forms of local peritonitis are due to muscular trauma.

The chief cause of appendicitis is trauma of the psoas muscle. The sigmoid and appendicular region is traumatized by the psoas muscle, the gall bladder region and that of the spleen by the diaphragm, its crura, and the abdominal walls. Muscular trauma on the tractus intestinalis makes a focus of lessened resistance and enables the rapidly multiplying germs or their products to penetrate the muscularis mucosæ, and enter the serosa. The most common cause of grave peritonitis is perforation of some hollow viscus, penetration of the abdominal wall, or infection conveyed through the blood.

The treatment of peritonitis consists in medical and surgical intervention. If it be medical, no drug equals opium in full doses, sufficient to arrest peristalsis. Rest, anatomical and physiological, is the all-important factor. This will corral the infectious atrium. The trouble, however, with opium is that its administration militates against subsequent surgical intervention; for it checks secretion.

After all, it should be noted that all cases of septic peritonitis belong to the domain of surgery. There are two methods by which surgical intervention succeeds in peritonitis, viz., drainage from the intestinal mucosa (cathartics), and draining from the serosa (incision). The best cathartics are, the mild chloride and magnesium sulphate, administered in small, often repeated doses. The best drain is the rubber tube wrapped in gauze.

The Pelvic Peritoneum lines the greater and lesser pelvic cavities. In the lesser pelvis the peritoneum intimately lines its lateral walls and floor, and invests more or less completely the contained viscera. The slippery, smooth, and elastic serosa enables the pelvic viscera to move freely, to return to normal after vast changes without loss of integrity, and to maintain the relation of physiology and anatomy among the pelvic organs. The pelvic peritoneum is a continuation of the lining of the abdominal cavity. Some deny a peritoneal covering to the ovary.

The pelvic organs appear as if thrust into the peritoneum from below, forming the peritoneal invaginations which enclose more or less of each organ. Beginning with the lower fold of the peritoneum on the anterior abdominal wall, one and a half inches above the crest of the pubis, the peritoneum reflects itself posteriorly on the summit and fundus of the bladder, covering this organ as far posteriorly as the level of the os uteri internum. The peritoneum covering the lateral surfaces of the bladder is limited by the abdominal hypogastric arteries. It covers the anterior surface, fundus, and the posterior surface of the uterus, whence it passes downward, covering the upper one-third of the posterior surface of the vagina. It then turns upward and backward to cover the rectum and sigmoid to the pelvic brim. Then, extending laterally from the border of the uterus, its two peritoneal blades enclose the oviducts, ovary and its ligament, vessels, nerves, muscles, and fœtal remnants. It then passes to the lateral pelvic walls. The diverging broad-ligament blades contain at their base the ureter, uterine artery, and pelvic brim.

In addition to investing the pelvic viscera, the peritoneum lines the lateral walls and floor of the pelvis. The peritoneum, covering the uterus, passes on each side to the lateral pelvic wall forming the broad ligaments which divide the pelvis into a posterior, larger and deeper fossa, and an anterior smaller and shallower fossa. The lowest portion of the posterior pelvic fossa is known as the pouch of Douglas, which is bounded superiorly by the folds of Douglas (utero-rectal ligaments). The peritoneal cavity is safely and easily opened through the pouch of Douglas. The peritoneum in the anterior pelvic fossa passes as low as the base of the broad ligament. The posterior pelvic peritoneal fossa is divided equally by the utero-rectal ligaments. The anterior pelvic peritoneal fossa is subdivided by the utero-vesical ligaments. The serous coat covering the uterus is the perimetrium; that covering the bladder is the perivesicum; and that covering the rectum is the periproctium.

The pelvic peritoneum rests on a large, thick, spongy, and extensive bed of snow-white subperitoneal

areolar tissue, on which the pelvic peritoneum with its invested organs glides and rests. The subperitoneal pelvic tissue allows contraction and expansion of organs, and the return to normal without loss of integrity. It is a buffer to prevent trauma, and it maintains with the aid of the pelvic peritoneum the relations of the viscera, nerves, and vessels.

The pelvic peritoneum does not completely invest all parts of the pelvic viscera. The anterior vaginal wall, the anterior surface of the cervix, the anterior surface of the bladder, the lower posterior (fourth) of the vagina, and lower portion of the entire rectum (anus) are not covered by peritoneum. The pelvic peritoneum is endowed with extensive elasticity, and freely accommodates the changing volume of viscera. Also the peritoneum is capable of being partially stripped from pelvic viscera and parietes.

When the bladder becomes distended, the peritoneum is not only dissected from the anterior abdominal wall, but also slightly from the anterior surface of the uterus. In pregnancy, the broad ligament not only becomes elevated above the normal, but the blades diverge and the peritoneum becomes drawn off the uterus. Some organs have loosely attached serosa, as the bladder and oviducts, the pelvic floor and parietes. The folds of the pelvic peritoneum form ligaments and pouches. There are six pelvic peritoneal ligaments, viz., broad, utero-rectal, utero-vesical, latero-vesical, utero-abdominal, and vesical superior.

The broad ligaments (ligamenta lata uteri) consist of (*a*) a thin layer of endothelia, permanent or temporary, on the anterior and posterior surfaces; (*b*) a mesenterii membrana propria which is the real neurovascular visceral pedicle. It is the mesodermic or permanent mesentery, carrying vessels and nerves to the viscera by means of the fibrous and connective tissue. This broad ligament extends from the lateral wall of the uterus to the lateral wall of the pelvis, immediately anterior to the sacro-iliac joint, subdividing the pelvic cavity. It is a secondary uterine support and serves chiefly to maintain in physiological and anatomical relations the contents of the broad ligament.

The two utero-vesical ligaments connect the lower portions of the uterus to the posterior surface of the bladder. They extend from the lateral portions of the uterus to the lateral and posterior surface of the bladder.

The utero-abdominal ligament extends from the cervix to the posterior abdominal wall.

The two utero-rectal (sacro-uterine) ligaments extend from the rectum (second and third sacral vertebræ) to the lateral borders of the internal os. These two ligaments being primary uterine supports must rupture or elongate before uterine prolapse or sacropubic hernia can occur.

The two lateral peritoneal vesical ligaments extend from the iliac fossa to the lateral surface of the bladder, where they join it at the line of the obliterated hypogastric arteries.

The superior peritoneal vesical ligament (ligamentum suspensorium vesicæ) extends from the summit of the bladder to the umbilicus. It covers posteriorly the urachus and the obliterated hypogastric arteries, which serve as a guide in peritoneal sections.

There are six peritoneal pelvic pouches or fossæ, viz., Douglas, utero-vesical, ovarian, paravesical, utero-abdominal, and vesico-abdominal.

The Douglas pouch, located between uterus and rectum, is bounded laterally by the utero-rectal ligaments, anteriorly by the posterior surface of the uterus and vagina, and posteriorly by the rectum. It is the most dependent part of the peritoneum; hence fluids will gravitate into it.

The utero-vesical pouch, located between bladder and uterus, is bounded anteriorly by the posterior surface of the bladder, and posteriorly by the anterior surface of the uterus.

The ovarian pouch, located between the uterus and the sacro-iliac joint, is triangular in shape, bounded in front by the base of the broad ligament, externally by the wall of the pelvis, and internally by the utero-rectal ligaments. This pouch is analogous to the ovarian pouch of animals.

The para-vesical pouch lies in the angle formed by the utero-vesical fold and the broad ligament.

The vesico-abdominal pouch exists when the bladder is distended.

The utero-abdominal pouch exists when the bladder is empty.

The pelvic peritoneum, with its folds and pouches, invests more or less intimately the pelvic viscera, maintaining them in proper relations, and facilitating perfect motion. It is relatively thicker in females than in males, and has become tolerant to peritonitis through the ages.

The pelvic peritoneum is not a dangerous region for lymphangitis (peritonitis), because it is limited in its capacity to absorb, due to relatively few stomata vera. Also fluids gravitate and remain in its most dependent portion, and visceral motion (peristalsis) being limited the infection is not widely distributed. With empty bladder, and the uterus lying in the anterior portion of the pelvis, loops of enteron lie in the pouch of Douglas. The enteron is the dangerous area of absorption (lymphangitis), but the few loops contained in the pelvis, becoming gradually infected, cease their peristalsis and throw out barriers of obstruction to the invading infection.

The pelvic peritoneum becomes infected primarily at the fimbriated ends of the oviducts, due to infection passing from the endometrium through the oviducts. Secondarily it becomes infected through the lymph and blood channels.

The etiology of peritonitis or lymphangitis must be attributed to pathogenic microbes and their products passing from the ovary, uterus, and especially from the oviducts. During the course of disease the serosa becomes reddened and hyperæmic, loses its shiny polish, leucocytes appear on the surface, the endothelia become desquamated, and an exudation appears on its surface. There is usually an endometritis, then an endosalpingitis, and finally a lymphangitis (peritonitis).

There may be scarcely any serum (dry form of lymphangitis), or there may be an abundance of serum (wet form). Should there be fluid present, the recent inflammatory lymph is usually suspended in the form of ragged flakes. The area of inflammation is coated with a reddish, elastic substance, known as fibrin, which lies loosely on some portion of the serosa (the serum may be encapsulated by peritoneal adhesion, and final absorption may occur). It extends in the form of threads and bands between opposed surfaces, or makes them adherent, binding the pelvic organs, colon, and enteron together by means of organized peritoneal adhesions. In severe septic cases, the exudation may be purulent. The chief element in the exudation is coagulated albumin, exudation fibrin, leucocytes, serum, and endothelial cells. For practical purposes there are four varieties of pelvic peritonitis, viz., (*a*) plastic, (*b*) serous, (*c*) septic, and (*d*) tuberculous.

Practically, the method by which pelvic lymphangitis becomes acquired is by the introduction of sepsis during coition, labor, abortion, or operations. Gonorrhœa produces plastic lymphangitis, but prepares the way for other forms of lymphangitis, by trauma that is due to staphylococcus, streptococcus, and tubercle bacillus. Catching cold at the monthly period means pelvic lymphangitis from sepsis forced out of the abdominal

end of the oviduct, when increased secretions have induced multiplication of germs, with perhaps raised virulence. Pelvic cellulitis generally is a result of lymphangitis passing into the subserosium, or it may be due to infection passing from the endometrium through the uterine wall into the cellular tissue at the base of the broad ligament. Tuberculous lymphangitis begins chiefly at the fimbriated extremity of the oviducts. Pelvic lymphangitis is the most serious gynæcological disease, because (*a*) it has a tendency to recur; (*b*) it produces severe pain; (*c*) it is a source of reflex neuroses; (*d*) it disturbs the mechanism of circulation and nerve distribution by traumatism of connective-tissue beds of the subserosium; (*e*) it produces atrophy of structures by fixing organs, causing an excessive local tension or slackness; (*f*) it produces adhesions binding the various adjacent viscera together, causing mechanical and functional disturbances; (*g*) it is almost incurable.

Woman suffers primarily from pelvic lymphangitis. A plastic pelvic lymphangitis may produce an exudate in size palpable only, or it may fill the lesser pelvis. The serous or purulent form may also fill the lesser pelvis with fluid or pus.

The most frequent variety of pelvic lymphangitis is the chronic plastic form whose adhesions produce fixations and dislocation of viscera, causing disturbances in anatomical and mechanical relations, impeding circulation, nutrition, and function, and causing nerve traumatism. The uterus, oviducts, the sigmoid, and the enteron may be found firmly bound together by organized cicatrizing peritoneal adhesions. A dislocated organ is one permanently fixed. As a rule, it is produced by peritoneal adhesions. Thus, after lymphangitis has swept over the pelvis, the uterus, oviducts, ovaries, sigmoid, and enteron may be found dislocated, fixed in various positions by the exudates. Some ligaments may be shortened, others lengthened, local peritoneal areas thickened, and viscera partially or completely buried by exudates. Sterility following pelvic lymphangitis is chiefly mechanical, due to separating the fimbriæ of the oviduct permanently from the ovary, preventing the transmission of an ovum to the uterus.

The Symptoms of pelvic lymphangitis are pain, and an acute or chronic course, with tenderness. The acute form may be ushered in by chill; rapid, small, wiry pulse; temperature 101 to 105° F.; nausea, vomiting, and tympanites. Constipation exists, and there may be irritability of the bladder and menorrhagia. In the chronic course there are tenderness, palpable exudates, pain, disturbances in the vesical, rectal, and menstrual functions. Leucorrhœa and menorrhagia are liable to exist. Irregular tympanites, indigestion, and anæmia, and finally neurosis play a significant part in the chronic form.

Bimanual examination discovers tenderness in the pelvis, with muscles on tension for protection, dry or moist vagina, with uterus, oviducts, ovaries with adjacent sigmoid and enteron generally bound in fixed masses of exudates. The vaginal fornices are sensitive and rigid, and all movements and pressure induce pain. Frequently the tenderness and size of the pelvic exudates prohibit examination. The most usual situation of the exudate mass is in the pouch of Douglas. The course of chronic pelvic lymphangitis of the recurrent type is serious to the patient's health, from constant irritation. The purulent form is grave while the plastic form may be recovered from. However, there is generally a residual exudate, with dislocation of viscera, giving rise to symptoms—especially pain and sterility. Pregnancy frequently cures pelvic lymphangitis by vigorous absorption during gestation. However, interruption of pregnancy is liable to occur, producing exacerbations. Pelvic lymphangitic exudates may result in absorption, encapsulation, inspissation, or cicatrization, which produce mechanical disturbances not only in adjacent but also in remote organs.

The Treatment of pelvic lymphangitis in the acute stage is: Place the patient in bed, and apply hot cornmeal poultices. For pain, give opiates and liquid diet; move the bowels by gr. i. of mild chloride every hour, for three to four hours, and ℥ ss. of magnesium sulphate every three hours. As the condition subsides, employ the vaginal (and rectal) douche morning and evening, gradually increasing from a gallon to five gallons; also increase the heat daily. Use the boroglyceride tampon twice weekly. The use of sounds, pessaries, repeated examinations, intra-uterine electricity, and massage should be avoided.

In the chronic stage employ the douche, tampon, massage, extra-uterine electricity, and general measures. Forcible reposition of the pelvic viscera, in lymphangitis, may be dangerous. Patients suffering with severe pelvic lymphangitis (peritonitis), being liable to exacerbations at menstruation, should rest in bed during the flow.

In cases resisting the reliable methods of treatment, the uterus should be removed. The ovaries, the essential of the genitals, should be left in order to avoid precipitate menopause. A patient fares better without the uterus and oviducts (the menstrual organs) than without the ovaries.

Gynæcological cases suffer chiefly from pelvic peritonitis. The pelvic peritoneum is supplied not only by sympathetic nerves but also by spinal sensory nerves, viz., (*a*) sensory branches of the ileo-inguinal, (*b*) sensory branches of the ileo-hypogastric, (*c*) sensory branches from the lower seven intercostals, and (*d*) to some extent branches from the sacral visceral nerves (third and fourth).

In certain pains of the tractus intestinalis, the seat cannot be accurately located. However, in appendicitis and pelvic peritonitis the seat of pain can be practically located. Traumatic pain of the peritoneum (non-inflammatory) is trifling, as the peritoneum on the digestive tract can be manipulated without symptoms of pain.

The non-sensitiveness of the normal peritoneum induces the Orientals, it is said, to slit open the abdomen to have a painless death. According to Hasse, the sensory nerves of the peritoneum are few. However, in an inflamed condition, the pain of peritonitis is a sad picture of a few distressful days. The pain in both general and local peritonitis is quite intense. In other organs similar conditions exist. Bone, muscle, and tendon are not very sensitive to incisions, but in an inflamed state are extraordinarily painful. Perhaps in peritonitis it is vascular spasm and vascular paralysis which are the base of the pain as in migraine. All coarse dragging or traumatism of the peritoneum is painful, as the breaking up of adhesions and ligation of peritoneal pedicles demonstrate.

The non-sensibility of the normal peritoneum and the intense pain of the inflamed peritoneum are not fully explained by the assertion that the connective-tissue cells, containing a sensory periphery, are isolated in health and in contact during inflammation.

While a pupil of Mr. Lawson Tait, he called my attention to severe pain in patieuts who possessed numerous peritoneal cysts located on the broad ligament. The cysts were perhaps remnants of previous peritonitis, and contained a yellow albuminous fluid.

Analogous, in part, are the oviducal herniæ. Since every viscus may become hyperæsthetic, the peritoneum, with an area equal to that of the skin, has extensive opportunities with its rich nerve periphery. Gubler's peritonismus is doubtless peritoneal hyperæsthesia. In clinical cases after visceral removal diffuse peritoneal hyperæsthesia persists. In the nerve periphery of the skin and mucosa we observe hyperæs-

thesia and anæsthesia. Why not, in the rich nerve periphery of the free peritoneal surface, find hyperæsthesia and anæsthetic zones?

The peritoneum invests such viscera as the spleen, stomach, enteron, ovary, cæcum, liver, and sigmoid so completely that they could scarcely be wounded without injury to itself. The kidney, right and left colon, uterus, oviducts, and bladder are partially uncovered by the peritoneum, and may be wounded without involving it. Inflammation of the viscera closely invested with the peritoneum, is followed by visceral peritonitis, as typically observed in the spleen, enteron, ovary, liver, and uterus. Viscera loosely or partially invested by peritoneum, may suffer severe parenchymatous inflammation without involving the peritoneum; as may be observed in the kidney, adrenal, right and left colon, posterior surface, oviduct, and pancreas. The loose subserous bed of connective tissue (mesoderm) on which the peritoneum rests allows it to glide about freely, and hence large abscesses may form from behind and burrow in various directions, finally discharging through the skin, without giving rise to peritonitis. The external surface of the peritoneum withstands inflammatory attacks to a remarkable degree, while the internal surface is very susceptible. Quarts of pus may be observed extending over large areas and in contact with the external peritoneal surface, for long periods, without fatal or even grave effects, while a single drop of the same pus coming in contact with the internal peritoneal surface would result in an immediately fatal peritonitis. The difference is between the structural apparatus and function of the peritoneal surface, and those of simple connective tissue. The posterior surface of the colon, right and left, or oviduct, may be perforated without involving the peritoneum, while perforations of the enteron or stomach will involve peritonitis.

Inflammation of the peritoneum, or rather lymphangitis, may lead to the formation of exudates, adhesions, and peritoneal bands, which are the cause of one-third of all intestinal obstruction. The peritoneal bands may strangulate or kink loops of bowel, fix viscera, and cause pain by checking peristalsis and visceral function. Much of the immediate and remote pain of laparotomy is due to peritoneal bands and adhesions from peritonitis, previous or subsequent to the operation. To relieve post-operative abdominal pain, reopen the abdomen aseptically and break up the peritoneal adhesions. The peritoneum is elastic and will allow very extensive stretching, if gradually performed, and still will return to normal. Examples are observed with large tumors and extensive ascites. Distention of the peritoneum may be observed in the sac of a hernia. The parietal peritoneum can be extensively torn without damage to viscera.

The great omentum is the surgeon's friend, which covers up the evil his hands have wrought. It is frequently exposed to trauma. It will quickly plug up small punctured wounds on the enteron and lateral walls of the belly. In a wound passing through the diaphragm, pleura, and intercostal spaces I saw parts of the omentum effectually plug the holes in the skin, found at an autopsy years subsequent to the injury. In another case I saw a large piece of omentum drag nine inches of transverse colon with it through an inguinal hernia. The omentum is frequently found in hernia, especially in umbilical, and in small pouches of median hernia above the umbilicus, causing considerable suffering. The omentum lies chiefly to the left side. It is an aid to diagnosis, since it fixes itself to original points of inflammatory invasions, at the hernial openings, abdominal ends of the oviducts, liver, spleen, appendix, and other points where visceral inflammation may arise. The omentum checks inflammatory invasion by surrounding it with exudates and matting organs together, and thus aiding to close visceral perforation. In gunshot perforations of the tractus intestinalis, I have observed it actually closing the wound. The omentum will nourish isolated tissue. Tumors whose pedicles have been twisted off by axial rotation may secure ample subsistence from the omentum. In hernia the omentum generally contracts adhesions to the bowel wall or sac, which thus becomes fixed; whence, by frequently dragging the omental band on the attached viscera, reflex and other disturbances will be produced. By its attachment in the hernial sac, or at the other points in the abdominal cavity, the omentum will form an arch under which bowel loops may become strangulated. Apertures should never be left in the omentum, as animal experimentation demonstrates that loops of enteron are very liable to pass through them and become strangulated. In several hundred autopsies I found the omentum covering the cæcum in some eight per cent. of subjects. It is an abdominal drain, and when it contains much fat it acts as a protector to the bowels. It prevents the bowels from becoming adherent to the anterior mobile abdominal wall.

The mesenteries are important in all abdominal and pelvic surgery, as they contain the blood-vessels, nerves, lymphatic vessels, and lymph nodes. They are the neuro-vascular visceral pedicles. The mesentery consists mainly of three layers, viz., (*a*) the middle, permanent, connective-tissue layer, containing nerves and vessels all woven together by connective tissue. This is the mesenterii membrana propria. (*b*) On each side of the mesenterii membrana propria or middle mesentery is a thin endothelial or peritoneal layer. The mesenteries divide the abdominal cavity into compartments, which aid in preventing fluids or infectious invasions from general distribution. The mesentery acts as a barrier, and each peritoneal compartment corrals its host. The mesenteron and meso-sigmoid aid in checking infections from passing upward. The mesocolon ascendens often corrals the pus of appendicitis between itself and the right abdominal wall, and with the aid of the colon transversum and ligamentum hepato-colicum circumscribes the infection which may emanate from the gall bladder. The ligamentum latum uteri frequently circumscribes the pus from the oviduct, preventing it from passing forward on the bladder, or upward into the enteronic loops—the dangerous grounds of peritonitis.

Practically, the mesenteron begins at the distal end of the duodenum, near the distal border of the pancreas, or second lumbar vertebra, whence it passes in an oblique line over the vertebral column, crossing the great vessels, and ending in an uncertain position in the right iliac fossa. The standard for the location of the distal end of the mesenteron should be the right psoas muscle. The left layer of the mesenteron is continuous with the right blade of the left mesocolon, and the right layer is continuous with the distal layer of the mesocolon transversum, and also the left blade of the right mesocolon. The left layer of the mesenteron passes over the sacral promontory into the pelvis, and also becomes the right blade of the meso-sigmoid. In several hundred personal autopsies the average length of the dorsal insertion of the mesenteron, the root, was about six inches, while the distance from the dorsal insertion of the mesenteron to its ventral visceral surface was six and one-half inches. The dorsal insertion of the mesenteron explains how hemorrhage, occurring on its right side, conducts the blood first into the right iliac fossa, while if the hemorrhage arises on the left side it will flow into the pelvis. The length of the mesenteron from spine to enteron varies in different segments of the tract from zero to ten inches, averaging six and a

half inches in women and seven in men. Practically the middle seven feet of enteron has the longest mesenteron, which allows the loops to fall into the pelvis or pass through some hernial ring (in ninety-eight subjects in one hundred).

The mesenteron is relatively long in infancy, shorter again in the second and third decade, after which it elongates every subsequent ten years, until the pronounced enteroptosis of old age exists. The root of the mesenteron and a large area of dorsal peritoneum may, after thirty years of age, gradually glide distalward, constituting visceral ptosis, which is accompanied by neurosis and deranged digestion. Herniæ are doubtless not so much due to visceral ptosis as to congenital and degenerative defects of the abdominal wall.

Apertures in the mesentery may arise, through which loops of bowel may glide and become strangulated. Mesenterial apertures are due to peritoneal defects, especially when irregular, and to trauma when slit shaped. Defective mesenterial apertures may be found about the lower ileum, due to lack of blood supply. The anastomosis of the ileo-colic branch of the superior mesenteric artery, with the right enteronic artery, circumscribes an oval area, poorly supplied with blood. It is an atrophic area with little or no fat, and the peritoneum becomes so thin that slight trauma produces an aperture. In peritonitis deformans the mesenteries may become practically obliterated. The mesosalpinx and mesometrium frequently become distorted or contracted from inflammatory processes, compromising circulation, compressing nerve periphery, and inducing trains of reflexes.

AMENORRHŒA.[1]

By L. H. DUNNING, M.D.,

PROFESSOR OF DISEASES OF WOMEN, MEDICAL COLLEGE OF INDIANA, UNIVERSITY OF INDIANAPOLIS; CONSULTING GYNÆCOLOGIST OF THE INDIANAPOLIS CITY HOSPITAL; CHIEF OF STAFF OF DEACONESS HOSPITAL, INDIANAPOLIS, IND.

Amenorrhœa may be defined as a permanent or temporary absence of the menses during the period of life at which they should be present. It has its causation in general states of the system or local pathological conditions of the sexual organs. Of the general states it may be said that the most frequent causes of amenorrhœa are those constitutional diseases which lead to the general impoverishment of the blood and to anæmia. Bright's disease is a frequent etiological factor, and in this disease the cause of amenorrhœa may be found in circulatory disturbances as well as in the anæmia always present. Tuberculosis is another common cause of amenorrhœa. Here the anæmia due to malnutrition and the exhaustive nature of the disease are the chief factors in bringing about amenorrhœa. So common a causative factor is tuberculosis, and so often is it mistaken for a result of amenorrhœa, that it is worth our while to pause a moment and consider more specifically the clinical aspect of amenorrhœa dependent upon tuberculosis.

The laity ascribe to the absence of menses a causation of pulmonary tuberculosis, and so great is their solicitude respecting the appearance of the sanguinary flow that they are continually importuning the physicians to re-establish this function, expecting thereby to turn aside or to cure the phthisis. Nothing could be more fallacious. The writer has been deeply impressed many times by the local pathological findings of cases of tuberculosis attended by amenorrhœa. He can best illustrate this subject by briefly relating the history of a case which came under his observation recently.

A young married woman, thirty-two years of age, came to the City Hospital for treatment because of the absence of menses and presence of great weakness. There were general pallor of countenance and slight cough, and also anasarca. No evidence of Bright's disease was found on examination of the urine, but an examination of the chest revealed extensive tuberculous involvement of one lung. The patient's anxiety to menstruate seemed to be emphasized by her great fear of pregnancy. There had been an absence of the menses for five months. The repeated efforts of several physicians to re-establish the function had failed. The physical examination of the pelvic organs revealed atrophy of all the organs of generation. The external labia were infantile, the vagina was small and short, the uterus was atrophied, and the ovaries were small; indeed, the general aspect of these organs was that of those possessed by a woman who had passed the menopause. This condition of the sexual organs is such as has forcibly attracted the attention of the writer upon many occasions, and is sufficient explanation of the futile efforts of many of us in our endeavor to bring about the restoration of the menstrual function in tuberculosis. The change of life which has taken place prematurely has resulted from the profoundly exhausting effect upon the system of the phthisis.

Chlorosis is another disease often attended by amenorrhœa in young women. This disease usually first manifests itself at puberty, and then only because of the unusual demand that is placed upon the circulatory and nutritive systems at the period of the secondary development of the sexual organs. While a deficient development of the arteries has undoubtedly been present from birth, yet this has not been manifested until now. The amount of hæmoglobin has been just sufficient to supply the ordinary demands, but now an unusual supply is needed. The system cannot furnish it. Anæmia results and the menses are not established; or if they have been partially established, they cease to appear.

Still another condition of the general state resulting in amenorrhœa may be found in those young girls living in an unhygienic environment, who take on rapid growth at the time of puberty. The air they breathe is impure, the food is insufficient, and their strength is taxed beyond their power of endurance. The result is anæmia, and the imperfect or retarded growth of the sexual organs; hence the absence of the menses until years beyond the time at which they usually appear.

The writer has not infrequently seen, and dares say his observations have been duplicated by many of the audience, young women who have suffered from amenorrhœa after acute attacks of scarlet fever and pneumonia. In due course of time, after the blood supply has increased and general nutrition of the body is restored, the menstrual flow is re-established.

Of the local conditions resulting in amenorrhœa I shall first mention atresia of the vagina or occlusion of the outlet from an imperforate hymen. This is a rare occurrence, but I dare say some of you have met with one or more instances of this kind. The writer is persuaded that amenorrhœa from complete occlusion of the vagina from a thickened and imperforate hymen is of very rare occurrence, inasmuch as he, after a somewhat prolonged and extensive practice, has never met with such a case. He has, however, met with one or two instances of partial occlusion of the vagina from an imperforate hymen and partial retention of the menstrual flow, but never an instance in which there was complete occlusion and retention. He once saw a marked case of uterus bilocularis with double vagina in which there was a minute opening in one

[1] Read before the St. Joseph County Medical Society, January 28, 1900.

vagina which allowed a very slow escape of the menstrual flow, so that oftentimes the vaginal tube was distended during the period of menstruation and for some time afterward.

The writer has also met with a curious case of atresia of the uterus and vagina, resulting from sloughing following the retention of a placenta. After healing, the woman never menstruated. For a little time this did not attract attention from the patient, but after a time, as the cicatrix became more dense, other troubles arose, and she sought relief. I saw her a few months after her confinement. The vagina was occluded, and there was every evidence of general atrophy of the sexual organs. I dissected my way through the tissue along the site of the original vagina until I reached the cervix uteri, which was also found occluded. No cavity could be found within that organ. The patient did not subsequently menstruate, and, in spite of the utmost endeavor, at the end of three months after the operation the vagina was again obliterated.

One of the most common causes of amenorrhœa in young women is imperfect development of the uterus or ovaries, or both, and it is surprising how frequently one who has much to do with this class of cases will encounter such imperfect development; and it is surprising, too, to note the characteristic marks that are often left upon the woman as a consequence of such imperfect development—as, for instance, in case of the absence or imperfect development of the uterus and ovaries, we will as a rule find stunted women, that is to say, women who have never reached physical perfection. We will observe it in their small hands and feet, small ears and nose, low stature, frequently in their infantile voice, and we will observe it, too, in the absence of those characteristics of anatomical development which are peculiar to the mature woman, namely, the broad pelvis and the rounded bust.

The writer has under his observation at present a patient who well illustrates these facts. She is nineteen years old, and has never menstruated. She is small, and while she has been engaged in outdoor work and has a ruddy complexion, yet she has the small hands and feet above referred to, childish voice, and general immature appearance. A physical examination shows an under-development of all the sexual organs, both external and internal. The uterus measures one inch in depth, the cervix is scarcely as large as one end of the finger. The proportionate size of the body and the cervix is nearly normal, showing that there is congenital atrophy of the organ. The ovaries, or what I took for ovaries on combined examination, are infantile. The curious thing about this case is that whereas the breasts are very nearly the size of those of a well-developed woman, yet the nipples are infantile. In other words, we have here that rare condition known as micromasia. In some instances in which there is an absence of the development of the sexual organs it will be found that the victim will possess many characteristics of the opposite sex, that is to say, in growth and general appearance. The voice is somewhat coarse, the chest is flat, the pelvis has the form of that of the male, and beard is likely to appear upon the face.

In not a few cases it will be found that in the development of the organs of reproduction there has been a blighting of the organs developed from the ducts of Müller, so that the Fallopian tubes, uterus, and vagina are either absent or rudimentary, and yet the ovaries are well developed. In these instances the woman may be well developed generally, and may possess all the external beauties of the female sex, and unless examined by a competent physician will be entirely unconscious of the extent of her deformity until united in marriage. The writer has met with two instances of this kind. The patients possessed sexual instinct and the menstrual molimen was present. There was, however, an entire absence of the menstrual flow; no vagina, and not a vestige of a uterus could be discovered upon combined examination. The ovaries, however, could be palpated through the rectum. My efforts to establish a vagina in these instances, while at first promising success, were in the end total failures.

There remains yet to be discussed another form of local lesion inducing amenorrhœa. It is that form in which there is atresia of the cervical canal, in which there are well-developed ovaries and a well-developed fundus uteri containing a cavity lined by normal mucous membrane. The atresia of the cervix may have been congenital or caused by localized inflammation, such as sometimes occurs during the progress of an attack of measles or scarlet fever, or may be due to an injury such as trauma or the application of caustics. Such cases as these are not of infrequent occurrence. In the old times of amputating the cervix for epithelioma when the thermo-cautery was employed, or when amputation was done by the knife and the stump treated by the Sims method, it was not an unusual occurrence to find after a year or two atresia of the os and the retention of the menstrual flow.

Suppression of the menses may occur in women who have been previously healthy. Not a few examples of this kind will be found in schoolgirls who are overworked or neglect to take sufficient exercise in open air. Women, too, who are subjected to prolonged mental strain are prone to become anæmic and emotional. Such women are very liable indeed to suffer from mental disorders.

Inflammatory lesions of the sexual organs resulting in suppuration are not infrequently associated with suppression of the menses. Here we may meet with perplexing difficulties in making a diagnosis. A woman presents herself complaining of slight fever, marked pain in the pelvic region, and an absence of menses. The breasts are enlarged and tender, the vagina is enlarged and purple in hue, and combined examination reveals a mass nearly filling the pelvis; and the uterus is movable with the mass—indeed, is a part of the mass. The organ cannot be isolated. The mass is elastic and boggy. The patient is evidently sick, but she has walked to the office or perhaps has travelled from a distant city.

In all my experiences as a practitioner in diseases of women, I have never encountered greater difficulties in diagnosis than are sometimes presented in such a case as this. The diagnosis arrived at after the most painstaking care has not always been entirely free from mistakes.

Recently in a patient who had been acutely ill for five or six weeks, who had had suppression of the menses for four months, in whose pelvis there was a mass of considerable size which was rapidly growing, and whose uterus was empty, the attendant physicians and myself diagnosed a double tubo-ovarian abscess. We operated through the vagina, when we encountered a three-and-a-half months' fœtus with its placenta, and all surrounded by a considerable amount of clotted blood. Fortunately our procedure was the proper one, and our efforts resulted in the rescue of the woman. In this instance there was not a clear history of rupture of the tubal pregnancy. Our diagnostic error lay in not being able rightly to interpret the meaning of a small amount of bloody serum drawn from the mass by plunging a hypodermic needle into it through the cul-de-sac. The needle-point entered the sac containing a blood clot and only a small amount of bloody fluid was obtained. This demonstrated mistake worked for me considerable good, for by the same means I have twice since

differentiated ruptured tubal pregnancy from a pus accumulation.

Double ovarian cysts are sometimes attended by suppression of menses, and if the cysts are not very large and the woman is quite fat, the physician will encounter almost insurmountable difficulties in diagnosis. In such cases the presence of fluctuation alone may be accepted as the determining point in the diagnosis. Every experienced gynæcologist has met with a considerable number of anomalous cases of amenorrhœa which are to him interesting and instructive. I will not weary you by reciting histories of many of them, but beg to present one.

Two or three years ago a young colored woman was sent to me, bearing a note from her mistress. The note ran as follows: "Please examine Fannie and write me your diagnosis. She is accused of being pregnant. She denies it and I am inclined to believe her, but her appearances are against her and she confesses to an absence of menses."

Upon external examination the abdomen was found enlarged to about the form and size of that of a woman six months pregnant. She confessed to me the absence of menses, but said she had never menstruated though thirty years old, and had not told any one, for she had a lover whom she desired to marry. She declared it was not possible for her to be pregnant. I examined her and found the tumor hard, nodular, and movable. The cervix uteri was very small, as was also the vagina. I accepted her statement that she had never menstruated, and passed a small sound into the uterus one inch. Two days later I removed a five-pound pedunculated, fibroid tumor of the uterus, and found the uterus and ovaries infantile. The tumor was subserous and pedunculated. The peduncle was not larger than the finger and not more than half an inch long, and was attached to the fundus of the uterus.

Treatment.—An efficient treatment of amenorrhœa must be based upon a correct knowledge of the lesion causing the absence of the menstrual flow. Our efforts to restore the function in Bright's disease and tuberculosis will be unavailing unless we can arrest and overcome the ravages of these diseases. Indeed, the writer would emphasize the fact that active efforts by the administration of powerful emmenagogues are harmful, for such a course is liable to result in congestion of the pelvic organs and the development of new and distressing symptoms without the hoped-for appearance of menstruation; and, furthermore, should the flow appear, it is prone to lead to greater anæmia, a condition which the attendant physician is using his best efforts to overcome.

Amenorrhœa following acute and debilitating diseases need not as a rule occasion the serious apprehension of physician and patient. Here the chief end should be to restore the health of the patient after the intensity of the attack has passed.

For the pale, anæmic, overgrown girls, the development of whose sexual organs is retarded, out-of-door sports wisely indulged in, together with the systematic administration of iron and arsenic, are generally efficient. In these cases, as the richness of the blood appears and the muscular strength develops, if the menstrual function is not established the stimulating properties of the faradic current may be utilized. Mild emmenagogues are often beneficial. Potassium permanganate in one- or two-grain doses is quite efficient. The intra-uterine application of the faradic current with the short, coarse wire and slow vibrations powerfully stimulates the muscular and circulatory activity of the uterus, and is quite an effective agent in restoring the menses when not dependent upon errors in development or constitutional dyscrasia.

Oftentimes a change of air, scenes, and surroundings will accomplish the greatest good. This is especially true in young women who are suffering from excessive mental work and worry. In all instances, hygienic laws must be observed.

The chlorotic patient may be expected to recover under the influence of appropriate treatment. Iron is the sovereign remedy, but it must be employed in conjunction with other measures.

Food rich in blood-making properties should be directed, and a high state of activity of the digestive and assimilative functions maintained.

It is highly important that the activity of the bowels should be secured. In case of constipation aloes when well borne may be counted the most efficient laxative. Scarcely less important is it that the functions of the kidneys and skin should be kept in normal condition. Tepid baths and friction of the surface of the body are beneficial, and free water-drinking between meals should be encouraged.

On account of circulatory and respiratory disturbances some chlorotic patients are unable to endure sufficient exercise. Here voluntary exercise may be supplemented by massage, Swedish movements, and surface electricity.

With the disappearance of anæmia and the oncoming of good health, the menstrual function is as a rule established. If it is not, the judicious use of the faradic current may be employed and mild emmenagogues administered.

The treatment of amenorrhœa due to occlusion of the vaginal outlet by an imperforate hymen is obvious. Incise the hymen, empty the vaginal tube, and pack lightly with gauze. Dilate fistulous tract in case of double vagina with partial occlusion of one, and dilate a stenosed os and introduce a Wylie drainage stem pessary, endeavoring by this means to secure a permanent patulency of the cervical canal.

When the amenorrhœa is due to retarded development of the sexual organs, if the patient presents herself early, before eighteen or twenty years of age, a reasonable hope may be entertained of establishing the menstrual function as a result of stimulating a growth of the reproductive organs.

Among the most efficient means to accomplish this purpose is the faradic current applied as indicated above. The prolonged administration of iron in small doses, or the iron and aloes pills, is not infrequently efficient. The use of the zinc and copper stem pessary, introduced by Simpson, is probably the most efficient mechanical means, especially in cases in which there is anteflexion of the uterus. In such cases the uterine canal should be dilated previous to the introduction of the stem pessary. There can be no doubt that while the method is often efficient, it is in some instances attended by danger to the patient. The pessary should be shorter than the uterine canal and of just sufficient size to be readily retained in the canal. If it produces the slightest pain or soreness it should be discarded.

A happy marriage, if the woman is otherwise healthy, not infrequently results in the speedy growth of the sexual system and occasionally in pregnancy. It must be remembered that in this class of patients the menopause is prone to appear early, and that miscarriage may occur in the first pregnancy, while a subsequent pregnancy may be followed by a perfectly normal gestation and delivery. In young women possessing highly atrophied uteri and ovaries we need not expect to see the menstrual flow appear, no matter what means are adopted. It is better to withhold all efforts in this direction. Occasionally in young women possessing well-developed ovaries and rudimentary organs developed from the ducts of Müller, life is rendered tolerable only by extirpation of the ovaries. This is a procedure the necessity of which is greatly to be deplored.

The Weight Curve in Infants.—Budin has given attention to the correlation between fluctuations in the normal weight increase of infants and their state of bodily health, and draws the following conclusions from his observations: A weight curve which steadily and regularly ascends is of great value as an indication of good health in infants, but can be taken only as a relative and not as an absolute sign. It often happens that children whose curve is faultless, syphilitics for example, suddenly die in the most unexpected manner. Children suffering from febrile diseases both of mild and severe grades frequently exhibit a weight curve which, instead of descending, rises steadily; these may recover, but are also liable to die. In some instances infants suffering from various disorders increase in weight suddenly and then die after two or three days; thus the author has observed an increase of 250 gm. in twenty-four hours and of 325 gm. in three days. Some of these infants suffer from a localized œdema, others urinate very slight amounts; the quantity of nourishment taken never exceeded the usual amount. This sudden and very marked rise of the weight curve in sick children is never a favorable indication, seeming rather to justify a hopeless prognosis.—*Annales de Médecine et de Chirurgie Infantiles*, June 15, 1900.

The Recognition of Embolism of the Pulmonary Artery.—Drasche reports a case of this interesting complication in which the diagnosis was made before death. The thrombus originated in the inflamed varicose veins of the lower extremities and passing into the auricle occasioned a temporary occlusion of the venous ostium. From this point it travelled into the right ventricle and lodged in the pulmonary artery, which by its gradual accretion was finally completely blocked, death resulting promptly. The symptom complex attending this casualty is sufficiently typical in the author's opinion to permit the diagnosis to be made without difficulty. The phenomena attendant on such a sudden interference with the circulatory mechanism are naturally most severe: syncope, loss of consciousness, convulsions, great restlessness and mental anguish, dyspnœa, cardiac arrhythmia, small or imperceptible pulse, cyanosis, clammy skin, and cold extremities. The physical signs exhibit the greatest variety, but a nearly constant sign is a humming thrill perceptible over the sternum in the neighborhood of the second and third intercostal spaces. At the same time peculiar sounds, rumbling murmurs that outlast the systole, are audible. In the case cited all of these were present, but subsided as suddenly as they had appeared, the patient almost entirely regaining control of herself, only to succumb fifteen hours later to another similar seizure. The author explains the temporary recovery as being due to the dislodgment of the thrombus from its site at the entrance to the auricle, while the long interval before the fatal ending corresponds to the gradual increase in size of the clot after reaching the pulmonary artery.—*Wiener klinische Wochenschrift*, June 7, 1900.

The Etiology of Multiple Sclerosis.—Under this heading Robert Gaupp discusses the question of the causation of this obscure disease. Rejecting as untenable most of the theories advanced, he considers the evidence of later years as pointing strongly toward traumatism of some sort as the primary etiological factor. Nevertheless, it is difficult to understand how a single injury can be capable of inaugurating a morbid process which often after a quasi-latent period of considerable duration continues to increase progressively for a practically indefinite length of time. It is also impossible directly to reconcile this theory with the anatomical findings, and the most rational view seems to be that either the continuous formation of some chemically toxic substance is caused, or that at the time of the injury the system at large is sufficiently disorganized to render it vulnerable to latent disease foci already present. It is in this way, perhaps, that most of the causes adduced (such as infectious diseases, acute intoxications, exposure, over-exertion, etc.) act, viz., by weakening the organism at large and particularly the nervous system. In confirmation of this view he reports at length the case of a machinist in whom all causative agencies could be excluded except a fall from a height of fifteen or twenty feet, which rendered him unconscious for a considerable length of time. Shortly after this he began to suffer from symptoms which gradually developed into those of a classical multiple sclerosis, and inasmuch as up to the time of the injury he had been perfectly well and had never been subjected to any other hardships, the author feels justified in considering the disease as a direct consequence of the trauma.—*Centralblatt für Nervenheilkunde und Psychiatrie*, June, 1900.

A Case of Unusual Cerebellar Tumor with Hydrops Ventriculi.—L. R. Morris reports a case occurring in a girl of six years. On autopsy the cerebrum presented no notable macroscopical changes except flattening of the convolutions. No tumor was visible until after a longitudinal incision through the corpus callosum and a separation of the hemispheres. Then there was exposed a brownish-red tumor, about the size of an egg, lying in the median line and touching the cerebellum. The lateral ventricles were opened and were full of a thin, reddish fluid; their surfaces were stained yellow. Projecting into the right ventricle from the foramen of Monro was a cyst, formed by the velum and filled with a bloody fluid. No further exploratory incisions were made at that time. There was about six ounces of fluid in the cranial cavity. The microscopical examination showed the tumor to have the structure of a small round-celled sarcoma augmented by repeated hemorrhages.—*Medicine*, July, 1900.

Sterility in the Male.—E. Ries makes a study of this condition, paying special attention to azoöspermia due to obstruction in the system of sperm channels. He makes two classes of cases, according to the presence or absence of changes in the cellular tissue surrounding the seminiferous tubules. The most marked of these changes is the formation of a zone of hyaline tissue around the seminiferous tubules in the place of the normal flat connective-tissue cells which form the physiological sheath of the tubules. This zone of hyaline tissue cuts off the epithelium from its supply of nourishment, normally derived from the blood-vessels of the intertubular connective tissue. Degenerative changes of the epithelium accompany the formation of the hyaline rings. Where the hyaline zone is thin we find the epithelium of the tubule either normal, even containing spermatozoa, or the spermatozoa are absent and we find only a few layers of epithelium, or even only one layer, the border-lines between the cells frequently becoming indistinct. There is, however, a distinct cavity of the tubule which is sometimes filled with spermatozoa. With the further encroachment of the hyaline zone the epithelium is reduced to a very thin, flat layer resembling endothelium, and these tubules contain nothing but a few fragments of cells. In the most pronounced cases the lumen of the tubule disappears completely, and instead of a channel lined with epithelium nothing is seen but a more or less wavy and hyaline mass of tissue with very few nuclei, without any trace of the normal testicular epithelium.—*Medicine*, July, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 28, 1900.

THE RELATIONS BETWEEN INFLUENZA AND CHRONIC DISEASE OF THE HEART.

AN abundant experience has shown that the poison of influenza, among other evil effects, is capable of exerting a profoundly deleterious influence upon the circulatory apparatus. It is well known that especially the aged and the debilitated are prone to fall victims and to succumb to the disease, and this result, it may be readily surmised, is principally attributable to influences acting upon the heart. An interesting discussion of the cardiac complications of influenza is entered upon by Schott (*Berliner klinische Wochenschrift*, 1900, Nos. 21 and 22), who points out that several groups of cardiac lesions in the course of influenza may be distinguished: (1) those due directly to influenza, (*a*) during the febrile course, (*b*) during a relapse; (2) those occurring as sequelæ; (3) those due indirectly to influenza, through disease of other organs.

Influenza gives rise most frequently to cardiac neuroses, both motor and sensory. These are generally attributable to the action of toxins, and although this is probably the correct explanation, it has not been determined with absolute certainty. Abnormally increased frequency of pulse is often attended with diminution in arterial pressure, with dicrotism, and with arrhythmia and allorrhythmia. The frequency of pulse often bears no relation to the temperature, being disproportionately greater than in other febrile diseases. Bradycardia occurs with unusual frequency in the sequence of influenza, but likewise in association with irregularity and inequality of the pulse, although less commonly with dicrotism, while lowered arterial pressure is not rare. There may further be alternation between tachycardia and bradycardia, sometimes in consequence of exciting influences, such as excessive physical activity, emotional disturbances, overloading of the stomach, and the use of alcohol, coffee, or tea; but at other times it may develop suddenly without obvious cause. These uncomplicated cardiac neuroses are by no means always free from danger, but they may be associated with weakness of the myocardium and dilatation of the heart. As long as the patient remains at rest the heart may exhibit no deviation from the normal on auscultation or percussion, but on slight mental or physical exertion the conditions are changed, and one or both ventricles may become dilated, and the first sound at the apex may occasionally be dull or impure on auscultation. Such a condition may persist for a long time.

The sensory neuroses occur less frequently than the motor in association with influenza, although even they are quite common. Little is known of vasomotor cardiac neuroses. Cardiac pain, in the form of pseudo-angina, as well as true angina, is, however, not infrequent. A neurasthenic condition of the heart is common. As already stated, the toxins of influenza may exert a directly injurious influence upon the heart muscle, and thus readily bring about conditions of exhaustion and relaxation, and thereby frequently myocardial weakness, especially as a result of carelessness, as from getting up prematurely, and exposure to cold and wet. Such conditions, unattended with further complications, may either disappear spontaneously, or yield speedily to appropriate treatment. With an unsuitable mode of life, however, permanent injury may result, with dilatation and all of its deleterious effects, and even fatty and parenchymatous degeneration of the myocardium may occur. The dilatation may give rise to relative insufficiency of the mitral valve, with a systolic murmur at the apex, and possibly, also, to relative aortic insufficiency. Influenza, further, may be attended with acute dilatation of the heart, and sudden death may follow.

Valvular disease of the heart, in consequence of primary endocarditis due to influenza, has been recorded by numerous observers, but it is more common as a result of disease of the pericardium, the pleura, the lungs, or as a complication of acute rheumatism. Disease of the myocardium is even a more frequent result from this cause. Old persons, and especially those presenting advanced arteriosclerosis, are exposed to especial danger in this connection, and a large proportion of deaths from influenza occur in such individuals. Other disturbances in the pulmonary circulation, such as may be induced by influenza, embarrass the action of the heart in part in a purely mechanical manner, and in part through chemical influences, such as accumulation of carbon dioxide in the blood. Those suffering from universal adiposis are predisposed to such disease of the heart, even in the absence of any trace of fat heart or of vascular alteration. Influenza may convert a mild variety of glycosuria into one of moderate severity, and it may render latent mellituria active, and thus affect the heart. Influenzal changes in the heart occur with relative frequency in cases of gout. The gastro-intestinal disturbances of influenza may induce enfeeblement of the myocardium in two ways—namely, through the resultant anæmia, and through distention of the intestinal tract, with more or less marked flatulence and displacement of the diaphragm upward. It is not definitely known, although it is possible, that the toxins of influenza exert a directly injurious influence upon the state of the blood.

Influenza most readily, and most rapidly, attacks a heart already diseased, altered, enfeebled, or irritated. The danger consists, not only in derangement of compensation, but also in renewal of the endocarditic process. Patients with congenital valvular disease,

or congenital deficiency of the inter-ventricular septum, are often destroyed within a short time, or present marked derangement of compensation. In the presence of myocarditis of arteriosclerotic origin, compensatory derangement and anginal attacks of marked severity occur in conjunction with more or less rapidly progressive inflammatory processes. Fat heart may be readily converted into fatty degeneration, and the enfeeblement may be marked. Attacks of syncope of longer or shorter duration may also occur, and thrombotic or embolic vascular occlusion may result. Not only are previously existing cardiac neuroses readily regenerated or aggravated by an attack of influenza, but the toxins also impair the muscular activity of the heart, and dilatation consequently results. The latter may, however, be due to other causes, such as insufficiency of nutrition during or immediately following the febrile influenzal period, especially in consequence of too exclusive a milk diet, and also after excessive doses of antipyrin, abnormally large doses of alcohol given with especial frequency, and over-irritation of the heart. Under such circumstances the state of relaxation is all the more marked. The debilitated conditions of the heart involve sometimes the right and sometimes the left ventricle, and sometimes both. The aggravations in the conditions of the heart induced by influenza are almost unexceptionally attended with lowering of the blood pressure.

THE NEED OF UNIFORMITY IN THE STANDARDS OF MEDICAL EDUCATION.

During the current year attention has been called on several occasions in the Medical Record to the question of interstate reciprocity in medical licensing, and the best means of bringing about this most desirable event has been touched upon. On February 10th in an article "Medical Education in the United States," the opinion was given that the National Confederation of State Medical Examining and Licensing Boards was the only body fitted by its composition to deal efficiently with the matter, and that to it must be left the solving of the problem, and the hope was then expressed that at its meeting at Atlantic City a discussion of the subject in all its bearings might tend to evolve order from the present decidedly chaotic condition of affairs.

We are glad to say that this hope has been realized to a considerable extent. The Confederation met in Atlantic City on June 4th, and the reciprocity difficulty was pretty thoroughly threshed out. Drs. William Warren Potter, of Buffalo, James A. Eagan, of Springfield, Ill., E. B. Harvey of Boston, J. N. McCormick, N. R. Coleman, of Columbus, Ohio, and others took part in the discussion. The agreement was unanimous as to the need of reform in the existing State medical laws, but the consensus of opinion was that any movement to this effect should be deliberate and well considered, and that nothing should be done hastily. The National Confederation appointed an interstate reciprocity committee consisting of the following members: Dr. Spurgeon, of Indiana, chairman; Dr. Amberg, of Detroit, secretary; Drs. Harvey, of Massachusetts, Korndoorfer, of Pennsylvania, and Swarts, of Rhode Island. The section on State medicine of the American Medical Association appointed an interstate reciprocity committee of three: Dr. Motler, of Washington, D. C., chairman; Drs. Amberg, of Detroit, and McIntire, of Easton, Pa.

That interstate reciprocity is badly needed will be allowed by all, but that under the present conditions it is impossible is a fact just as indisputable. The first steps to be taken is the introduction, as far as is possible, of a uniform standard of medical education throughout the country. Mr. James Russell Parsons, the author of an excellent monograph on the subject, suggests, as a uniform standard for admission to medical practice in all parts of the United States is at present impracticable, that instead of the adoption of a separate standard for almost every political division two, or at most three, standards should answer for all. One phase of the situation is both noteworthy and satisfactory: the members of the medical profession of this country are becoming more and more alive to the incongruity, not to say absurdity, of the existing methods of medical education in the various States. After all, the remedy lies in their own hands. If they determine that the standards shall be raised and placed upon a uniform plane, all obstacles will quickly melt away.

THE "NEW YORK MEDICAL JOURNAL" CHANGES OWNERS.

The ownership of the *New York Medical Journal* has passed from the publishing-house of D. Appleton & Company to Mr. A. R. Elliott, an advertising agent of this city. We understand, however—we certainly hope—that the editorial department will remain in charge of the present editor, to whose able management for so many years the journal owes its high professional standing. This change has been anticipated for some time, for it was learned last spring, at the time of the temporary embarrassment of this old and honored publishing-house, that some of their publications, notably the *New York Medical Journal*, were financially unprofitable. Notwithstanding an actual subscription list of something over six thousand, and an advertising patronage of upward of forty pages per week, the expenses of publishing this journal were considerably in excess of the income from all sources, and the receiver, therefore, decided to dispose of the property, with the result above stated.

It will doubtless be a matter for surprise to the great majority of the profession to learn that a medical journal apparently so prosperous was financially a failure, and it will perhaps dispel the idea which seems to prevail that the profits of publishing medical journals are fabulously large. Those who have had experience in such matters know well that the publication of a medical journal is very different from that of an illustrated magazine for the general public. The latter can be sold at a price irrespective of the cost of manufacture, and thereby secures an enormous circulation, the profit on the undertaking being derived

wholly from the advertisements. The number and variety of the latter which can be secured for a monthly magazine are practically unlimited, whereas in the matter of reputable medical advertising there is a very sharply defined limit. This change of ownership of the *New York Medical Journal* may serve to impress the truth of the facts just stated upon the minds of the more or less experienced financial backers of some other of our contemporaries which are now being published at a heavy loss.

News of the Week.

Yellow Fever in Cuba. — During the first half of July there were forty-five cases of yellow fever reported in Havana, with sixteen deaths. Nearly all of the patients were newly arrived Spaniards, very few being Americans. A woman who arrived at this port last week in a steamship from Havana was found to be suffering from yellow fever and died at quarantine the day after her arrival. In a despatch to the War Department from Havana, it is reported that General Lee has obtained information that leaves no doubt about the existence of yellow fever among the troops at Pinar del Rio, and that nine deaths there last month, reported as pernicious malarial fever, are now believed to have been yellow fever. Surgeons sent to Pinar del Rio to make an inspection have reported that yellow fever exists among the troops. The despatch also says that there are five suspected cases of yellow fever among the soldiers stationed at Guanajay.

Jubilee of the St. John's Guild.—The twenty-fifth anniversary of the beginning of the floating-hospital service of St. John's Guild was celebrated last week, when the members and officers of the Guild and their friends took a trip down the bay with the children on the *Emma Abbott*, had a luncheon and appropriate exercise on board, and returned to the city later on the *Helen C. Juillard*. The first trip of the *Emma Abbott* was made on July 19, 1875. The *Helen C. Juillard* was put in commission last summer. The trained-nurse department was started in 1887, and the salt-water bathroom on the floating hospital the following year.

Infant Mortality in Brooklyn.—It was stated recently in a Brooklyn newspaper that the mortality among children under five years of age is greater in that borough than in any city in the United States, and very much higher than in Manhattan. The main reason for this difference between the two boroughs is alleged to be that there is no summer corps of physicians to visit the tenements in Brooklyn, prescribe for sick babies not under the care of a physician, and instruct the mothers in the elementary rules of hygiene.

Smallpox Outbreak in Montreal.—Owing to an outbreak of smallpox the board of health of Montreal has ordered house-to-house vaccination. Within the last two weeks there have been a dozen cases, four of which terminated fatally. They are all in the good English residence district.

The Prevention of Premature Burial.—The American Society for the Prevention of Premature Burial, which is modelled on about the same general lines as the London society of the same name, has been organized in this city. The founders of the society are Mr. Clark Bell, Dr. Thomas Darlington, Dr. Henry J. Garrigues, Mr. Cyrus B. Gale, and Mr. H. Gerald Chapin.

Measles on a Naval Training-Ship.—The naval training-ship *Newport* returned from Boston to Newport recently with several suspicious cases of measles on board. During the previous visit of the *Newport* there an epidemic of that malady developed, and the cadets sick at the time were sent to the Naval Hospital, on Coasters Island. All recovered, and the ship sailed with the belief that the sickness had entirely disappeared.

Heroic Therapeutics.—It is reported that as the result of a fall from the roof of his house speech has been restored to a man in Pittsburg who for fifty years had been unable to express himself in other than the sign language. The remedy seems an unnecessarily violent and dangerous one when it is known that hysterical disorders, as this can only be, are often readily and as efficaciously relieved by less vigorous suggestive treatment, such as bread-pills, hypodermic injections of water, applications of electricity, the laying on of hands, prayer, and other more recent and more fashionable delusions.

A New German Hospital Building will soon be erected at the corner of Lexington Avenue and Seventy-seventh Street. The cost of the new building, and of alterations to the building adjoining this site, and now used as the woman's ward of the hospital, will be $150,000.

Scholarships of the American Medical Association.—In accordance with the recommendation of Dr. Keen in his presidential address, the trustees of the American Medical Association have established a fund of $500 to be expended annually for the encouragement of scientific research, but no sum given to any individual shall exceed $100 at one time.

The Faith-Cure Fad.—It is stated in the *Medical Sentinel* that there are twice as many persons studying in the so-called schools of mental healing, faith cure, Christian science, and the like, than in all the medical schools in the country combined.

The Second Cuban Medical Congress, which was to have been held in Havana the last week in February, 1901, has been postponed to a corresponding date in 1902. This action has been determined by the resolution of the international executive committee to hold the third Pan-American Medical Congress in Havana in December of the present year.

Dr. George O'Hanlon, of King's Park, has been appointed first assistant physician at the Long Island State Hospital.

"Archives de Médecine et de Chirurgie Spéciales" is the name of a new monthly journal of Paris, established and edited by Dr. Suarez de Mendoza. It is a sort of review of reviews of the specialties in medicine.

Care of Lepers in Louisiana.—The State legislature of Louisiana has added $5,000 to the $20,000 appropriated one year ago to purchase the site and erect suitable buildings for the care and treatment of the lepers of the State. The present hospital is only leased for a definite time and is inconveniently situated. The board of control of the Leper Home intends to purchase a site as near New Orleans as possible, in order that every facility may be had for treating these unfortunates. The board applied for an increase of $20,000, but succeeded in getting but $5,000.

A Deserting Russian Naval Surgeon.—Dr. Leo Alexandroff, an assistant surgeon in the Russian navy, was sent to Philadelphia recently with a crew of sailors to man the cruiser *Variag*, which has just been built here for the Russian government. On arrival here he deserted, but was arrested at the instance of the Russian vice-consul and was held to await requisition papers. It was contended that he was simply a deserter from the navy and not from any particular vessel, and that therefore his case was not provided for in the treaty relating to deserters from naval vessels. The United States district judge, before whom the case was tried, discharged the prisoner on this ground, but the counsel for the Russian government immediately took an appeal to the United States court of appeals, and Dr. Alexandroff was held in bail pending a decision of that court.

The Spitting-Nuisance in Atlantic City.—The board of health of Atlantic City has declared spitting in public places, in cars or 'buses or any conveyance, or on the boardwalk or any sidewalk, a nuisance, and any person, persons, or corporation making, causing, maintaining, or permitting any such nuisance shall forfeit and pay a penalty of $20.

Faith-Cure in Philadelphia.—The coroner of Philadelphia has committed for trial a man under whose care death occurred in an infant seven months old, from convulsions during teething, as a result, in the opinion of the coroner's jury, of criminal neglect. The offender claimed to be one of the "children of God," believing in the "cure of disease by prayer." Hence the services of a medical man were not sought. Even incarceration was without terror, from a sense of "deliverance through faith."

Philadelphia Hospital.—Dr. Emanuel S. Gans and Dr. Milton B. Hartzell have been elected dermatologists to the Philadelphia Hospital, in succession to Dr. J. Abbott Cantrell, resigned.

Mortality Statistics in Philadelphia.—For the week ended July 21st, there were reported to the Philadelphia bureau of health 564 deaths, being 31 more than for the preceding week and 41 more than for the corresponding week of the previous year. Of this number 17 were due to sunstroke, 89 to cholera infantum, and 23 to inanition in infants. Among other causes of death are: pulmonary tuberculosis 45, gastro-enteritis 42, marasmus 34, convulsions 30, heart disease 27.

A Fertile Source of Typhoid-Fever Infection has been found in the handling of the well-rope or chain by those in attendance upon a typhoid patient. Such being the case, physicians practising in country districts should see to it that these attendants do not draw water from the well. It is easy to see how a whole family may be infected by the drinking-water when such infected hands have been literally washed in the well. Those familiar with the very common mode of raising water from wells by the bucket system will readily appreciate the force of this suggestion.—*Richmond Journal of Practice*, June, 1900.

First Steps in Medical Reciprocity.—At a regular meeting of the State board of medical examiners held at Newark, N. J., July 5th, a resolution was adopted that the board will hereafter indorse the licenses of any State board of medical examiners in the United States, in lieu of an examination, provided that the candidate for indorsement shall present satisfactory evidence of having the academic and medical education required by the New Jersey State board, and that the license presented for indorsement shall have been issued after a State examination of the same grade and kind as that required in New Jersey.

A Seasonable Procedure.—In its unbounded zeal and enthusiasm a Philadelphia homœopathic medical society continues its monthly meetings during the heated term; but temperatures of 100° and thereabouts are not conducive to a large attendance and an interested audience. So, adapting itself to the circumstances, this modern and progressive society engaged a steamboat for its July meeting, and those who were loyal and fortunate enough to attend were regaled with river breezes while listening to scientific discourse.

Typhoid Fever at a Golf Club.—Alarm has been caused among the members of a golf club near Chicago by an epidemic of typhoid fever which has claimed as victims nearly fifty persons who frequented the club's greens. Thirty-three caddies are suffering with typhoid fever and one has died. Ten employees of the club are confined to their beds, one club member has died, and three more have been stricken. The water of a well on the links was much used by the golfers in preference to the regular supply for the club, which is drawn from artesian wells. When the outbreat of typhoid fever occurred, suspicion was directed to this well, and a bacteriological examination of the water showed the presence of Eberth's bacillus.

A Day Nursery.—Plans have been filed by the Brightside Day Nursery and Kindergarten of this city for a new building, five stories in height, to be erected on Cannon Street, near Rivington.

Disease at Nome.—According to the reports of travellers returning from Nome, the sanitary condition

of that place is very bad, smallpox, typhoid fever, and pneumonia being epidemic. A Chicago physician is quoted in the papers as saying that things there "are fast approaching a frightful crisis. Everything is polluted with disease. Water is filled with filth and deadly germs. The beach for six miles is filled with disease. Here and there can be seen danger signals flying from tent poles. As the pest house is full, many smallpox patients are being cared for in their tents until the government houses are completed. People are dying within forty-eight hours after being taken ill with pneumonia. Officials at Nome are sending out orders for one thousand cots for use in hospitals that are being built. They are to have a pneumonia hospital and a separate hospital for smallpox. Outside of the regular physicians, it is almost impossible to get men to work in the pest house, even at $2.50 per hour, which was being offered."

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending July 20, 1900. July 14th.—Medical Director P. Fitzsimons detached from the naval examining-board, Annapolis, Md., and ordered to duty in charge of the naval hospital, Newport, R. I., July 21st. Medical Director H. J. Babin detached from duty as president of the medical board of examiners, naval laboratory, Brooklyn, N. Y., July 25th, and ordered home and to wait orders. Surgeon L. G. Heneberger detached from the naval hospital, Newport, R. I., July 21st, and ordered to duty as member of the board of medical examiners, naval laboratory, Brooklyn, N. Y., July 25th. Passed Assistant Surgeon A. M. D. McCormick detached from the *Chicago* and ordered to the *Montgomery*. Assistant Surgeon J. R. Whiting detached from the *Montgomery* and ordered to the *Chicago*. Assistant Surgeon C. N. Fiske detached from the navy yard, Boston, and ordered to duty with marines at San Francisco, Cal., and then to duty at the naval hospital, Mare Island, Cal. Assistant Surgeon J. H. Payne, Jr., detached from the naval hospital, Mare Island, Cal., and ordered to the Asiatic station with the fifth battalion of marines. Pharmacist A. Prosperi detached from the naval academy, July 21st, and ordered home and to wait orders; retired from July 3, 1900, under the provisions of section 1,143, Revised Statutes, upon his own application, after forty years' service.

The "Archivos de la Policlinica," a medical weekly publication of Havana, has suspended publication. It was established eight years ago, and has been ably conducted by Dr. Enrique López and a staff of collaborators.

Obituary Notes.—Dr. Divie Bethune McCartee, a pioneer among medical missionaries, died in San Francisco on July 17th, while on his way to this city from Japan. Dr. McCartee was born in Philadelphia on January 13, 1820, and was the eldest son of the late Dr. Robert McCartee of this city. He attended Columbia College, and then went to the University of Pennsylvania, from which institution he received the degrees of A.B. and M.D. He began the practice of medicine in Philadelphia, but in 1843 went to China and opened a medical mission in Ningpo early in the following year. He lived in China for forty years, mastering so perfectly the official language of the country and several of the dialects that he was employed as interpreter in the local Chinese courts. The Chinese government gave him a gold medal in recognition of his services in connection with the suppression of the Macao coolie traffic, and later he received the title of consul-general for services in the Chinese legation. He afterward went to Japan and worked as a missionary there, and became so proficient in the language that his services as interpreter were made use of again by this government. He was decorated by the Japanese emperor with the order of the Rising Sun. His widow survives him.

Dr. Samuel Russell Welles died at his home in Waterloo, N. Y., July 13th. He was born in Waterloo, February 23, 1825; was graduated from Geneva College (now Hobart) in 1845, and received the degree of M.D. at Buffalo University in 1848. In 1862 he entered the military service as acting assistant surgeon in the Sixty-First Regiment, New York State Volunteers, and received a commission in March of that year. In 1875 he was elected a trustee of Hobart College, and was twice sent to the legislature from Seneca County.

Dr. Elias S. Peabody died at his home in Taylorville, Ill., on July 20th, at the age of eighty-seven years. He was born in Stonington, Conn.

Dr. Clitus S. Hoag, of Bridgeport, Conn., died on July 18th, aged forty-five years. He was a graduate of the Hahnemann Medical College, Philadelphia, in 1877.

Dr. Oswald B. Finney died at his home in Onancock, Va., on July 23d, at the age of nearly eighty years. He was a graduate of the medical department of the University of Pennsylvania in 1843.

Dr. Charles H. Mersereau died on May 2d, of heart disease, at his home in this city. He was thirty-seven years old and was unmarried. Dr. Mersereau was born in Port Chester and was graduated from the College of Physicians and Surgeons in 1884. He served two years in the Hartford, Conn., Hospital, and for several years was sanitary inspector in this city.

Dr. James S. Gillespie died of appendicitis at Philadelphia on July 19th, at the age of thirty-seven years. He was graduated from Jefferson Medical College in 1884, and became a resident physician in the Jefferson Medical College Hospital.

Dr. Thomas Story Kirkbride died of typhoid fever at Philadelphia on July 19th, at the age of thirty-one years. He was a son of Dr. Thomas S. Kirkbride, the distinguished alienist, who was for more than forty years the superintendent of the Pennsylvania Hospital for the Insane. He was graduated from the medical department of the University of Pennsylvania in 1893, and in 1894 became a resident physician in the Pennsylvania Hospital. On his return from post-graduate study abroad, he was in 1897 appointed director of laboratories in the Philadelphia Polyclinic. He was also assistant physician to the University Hospital and assistant pathologist to the Philadelphia Hospital.

Progress of Medical Science.

The Boston Medical and Surgical Journal, July 19, 1900.

General Remarks on the Pathology and Symptomatology of Acute Pelvic Suppurative Processes in the Female, and their Treatment by Posterior Colpotomy.—Charles Greene Cumston says that an experience of more than six years in vaginal work has proved to him that posterior colpotomy is a very innocent operation, and in the highest degree conservative. It may be performed not only in cases of acute purulent lesions in the pelvis when it would be imprudent, not to say dangerous, to perform laparotomy or vaginal hysterectomy, but also in cases of chronic purulent pelvic lesions. It should be preferred in every case in which the patient is a young woman, it being the surgeon's duty to preserve the adnexa at any cost. Every suppurating pelvic collection that is accessible by Douglas' cul-de-sac is suited for posterior colpotomy and drainage. The author describes the technique of the operation.

Parturition Complicated with Suppurating Fibroids.—E. H. Stevens reports a case in which labor was normal, in spite of a uterine fibroid. Symptoms of septic infection developed, and injections of antistreptococcus serum were given. A complete hysterectomy was performed on the seventeenth day after labor. Death occurred on the twenty-first day. The author says that all the surroundings of the patient were aseptic, so that he does not see how anything more could have been done to prevent the tumor from becoming septic. As to the operation he would not hesitate to advise it in any similar case. The injection of the serum, he thinks, did no good, and probably did harm, as evidenced by a rash. There was no evidence of streptococcus infection, and therefore the use of the antistreptococcus serum was irrational.

Glandulopenile Hypospadias; Two Urethras, One Extending to the Bladder, the Other Two and One-Half Inches Long, and Terminating in a Blind Pouch.—By J. Coplin Stinson.

Milk; its Production, its Care, its Use.—By J. M. Rotch.

Medical News, July 21, 1900.

Appendicitis and Typhoid Fever.—H. A. Hare refers to two groups of cases which have never failed to puzzle him: (1) Cases in which symptoms, appearing in the neighborhood of the appendix, indicate the rapid development of appendicitis, yet in which these symptoms gradually subside and the patient passes into an attack of typhoid fever; (2) cases already well advanced in the progress of typhoid fever which develop appendicular symptoms. Histories relating to each are given. In one the symptoms were typical of appendicitis, and operation was about to be done but was postponed. At the end of a week typhoid fever was fully developed. The possibility of typhoid infection of the appendix producing appendicitis is mentioned. In a boy aged nine years, the symptoms of appendicitis disappeared under ice-bag treatment and typhoid developed. He regards appendicular trouble in the early stages of typhoid as by no means rare. Ulceration in the neighborhood of the caput coli can readily produce tenderness, resistance, and other symptoms of appendicitis. Much attention should be paid to blood examinations.

The Continued Use of the Antiseptic and Eliminative Treatment of Typhoid Fever Without Any Deaths.—T. Virgil Hubbard, when called to a case of typhoid fever, usually commences by giving the patient a capsule containing calomel, gr. ss.; guaiacol carbonate, gr. ii.; podophyllin, gr. $\frac{1}{50}$ to $\frac{1}{10}$, every two hours for twenty-four to forty-eight hours, depending on the condition of the bowels. He continues this until he has secured four or five intestinal evacuations for two successive days, and then stops administering the calomel and adds gr. ss. of menthol to the guaiacol and podophyllin. Small doses of salts or Hunyadi water are given if there is a tendency to inactivity of the bowels. Decinormal salt solution is given per rectum when the skin and kidneys fail to act well. The proper administration of calomel is the point to which he desires to call especial attention, *i.e.*, small and often repeated doses. A typhoid patient can take more mercury without purgation or salivation than the same individual in health. He has treated twenty patients without a death.

Moulds in the Stomach.—J. H. Kellogg found in seven thousand analyses mould present four hundred and fifty-seven times. The sources of moulds in food are numerous. Like various bacteria they give rise to fermentations and putrefactions. They grow in acid media. In the cases noted simple dyspepsia was present thirty-two, hyperpepsia one hundred and seventy-six, and hypopepsia two hundred and forty-nine times.

Iodide of Iron in the Treatment of Certain Forms of Infective Arthritis.—J. C. Wilson has for several years treated all cases of gonorrhœal arthritis with large doses of the syrup of the iodide of iron. Cases are reported. The subject belongs to the realm of empirical therapeutics.

New York Medical Journal, July 21, 1900.

Syphilis of the Brain.—J. T. Eskridge concludes a lengthy article with remarks on diagnosis and treatment. The latter is considered under the headings of prevention, general management, and anti-syphilitic medication. His experience has been that the activity of the syphilitic process is the only guide to the choice of mercury or potassium iodide. The greater the activity of the poison, the more acute and violent the symptoms, the greater the demand for mercury. On the other hand, potassium iodide apparently does more good in the chronic specific process than does mercury. He does not wish us to infer that mercury does no good in chronic syphilitic lesions and that potassium is useless in the active and acutely irritative ones. On the contrary, he believes that each may be indicated in almost any stage of intracranial syphilis; but when it is a question under which drug's influence we must first seek to bring our patient, then the acuity or chronicity of the syphilitic inflammation should guide us.

The Etiology and Cure of Hysteria.—F. Walter states that if a massive culture of the colon bacillus, the original colony of which was taken from a non-infectious source, be administered to a case of hysteria—that is to say, of the active or convulsive type—latent or post-hysterical phenomena such as paralysis being excluded, the symptoms disappear in from twenty-four to forty-eight hours and the patient is restored to health so far as the hysteria is concerned; debility or neurasthenic phenomena may remain for an indefinite period. As to etiology, two views may be propounded: one assumes the existence of a specific organism causative of hysteria not to be differentiated by our present methods from the bacillus coli communis; the other, that in the intestinal tract of predisposed subjects the otherwise harmless colon bacillus may take on toxic properties. In either event the offending organism is simply displaced by the method of treatment here advocated.

The Prevention of Colds in the Newborn.—L. B. Lockard finds the chief requisites on the part of the future mother to be a careful diet, loose warm clothing, daily exercise in the open air (omitted in the later months of gestation by most women because of a sense of false modesty), daily bathing in lukewarm water, and mental entertainment. These directions are of cardinal importance as preparing the way for the birth of a strong, vigorous child. Then, during the very first weeks of infancy, and from that time on, special attention should be paid to the clothing, and the dwelling should be kept at a proper temperature. All overstimulation in every direction must be forbidden, while careful attention must be paid to bathing and exercise.

A Brief Consideration of Gangrene and Mortification (Traumatic and Pathological) of the Extremities.—By T. H. Manley.

The Pituitary Gland as a Factor in Acromegaly and Gigantism.—By Woods Hutchinson.

Journal of the American Medical Ass'n, July 21, 1900.

Surgery of the Tear Passages.—J. G. Huizinga describes the characteristics of catarrhal inflammation, infections, and strictures of the lacrymal canal. The treatment of stricture is comparatively simple because of the ease of access. The opening into the canaliculus is not always easy for the inexperienced. If a large portion of the canal is closed, it becomes necessary to make an opening a short distance beyond the punctum near the median line just within the upper or lower border of the lid. The tendency to heal must be prevented by the daily use of a well-lubricated No. 6 probe introduced as far as the sac. In simple contraction he prefers the rapid method of dilatation. He agrees with Knapp that patients with moderate epiphora should bear their trouble without probing. Slitting the canal and converting it into a groove is as unscientific as its results are unsatisfactory. Simple dilatations of the

constricted portion of the canaliculus by means of ordinary probing alone is notoriously unsatisfactory. If after a careful examination it has been ascertained that the obstruction to the canal is of a bony nature, the treatment resolves itself into extirpation or complete destruction of the lacrymal sac, with or without excision of the lacrymal gland.

Acute Tonsillar Diseases and their Sequelæ.—J. H. Abraham describes superficial tonsillitis, cryptic tonsillitis, and peritonsillar abscess. Tonsillitis due to milk infection, to disordered stomach from overfeeding in children, and to faulty drainage is mentioned. Treatment is given at some length. The author's conclusions are: (1) All cases of acute tonsillar disease should be considered more than trivial affections. (2) Acute lacunar tonsillitis is an infectious disease. (3) Isolation should be practised in all cases of acute lacunar tonsillitis. (4) Recurring attacks of acute tonsillitis are an indication for the partial or complete removal of the tonsils. (5) A careful systemic examination and treatment should be applied during and after an attack of acute tonsillitis.

The Differentiation of Chorea and the Disorders Simulating it.—Augustus A. Eshner finds that in chorea we have a suggestion of an infectious process, although the cause has not been fully determined. Various irritations which play a part in the forms of spasmodic tic have no bearing upon true chorea. The apparent relations between chorea and rheumatism are still obscure. Mircoli concludes from investigations that both are dependent on infection with pyogenic cocci which do not give rise to suppuration. The distinctions from habit chorea, mimic spasm, senile chorea, hysteria, torticollis, nodding spasm, etc., are pointed out.

Value of the Angiotribe in Vaginal Cœliotomy.—J. H. Carstens refers to the difficulties of removal of the ovaries by the vaginal route and points to the great aid of the angiotribe in these operations. The instrument he prefers, that of Thuman, has a narrow blade of great strength and is provided with a small handle lever instead of a wheel. It is less difficult to apply and holds in exact place better than others he has tried.

Peritonitis in the Fœtus.—J. A. Porter reports a case of somewhat difficult labor occurring in a woman twenty-five years old. The child gave one or two unnatural respiratory movements and died, all attempts at resuscitation being in vain. The abdomen was very large; the peritonal cavity was found to be filled with a brownish-green fluid. The intestines were matted together with soft lymph adhesions, and the mesentery and peritoneum were deeply congested.

Some Unusual Sequelæ of Epityphlitis.—A. E. Barker gives a series of cases showing that when we delay to operate the pause must not be too protracted. There is often unnecessary haste, but in many other instances delay is a terrible mistake. The first case illustrates the development of subphrenic abscess as the result of epityphlitis, a complication probably more frequent than is commonly supposed. Sonnenburg met with this complication nine times in six hundred cases operated on by himself. The second case also emphasizes the danger of lung complications from either extension of the inflammation around the cæcum upward to the under surface of the diaphragm, or of infarcts lodging in the lung and producing an abscess there. The third case shows the disastrous local results of leaving a perityphlitic abscess too long unopened, and the way in which the resulting "artificial" anus may be brought to heal. The fourth case illustrates a form of ulceration due to concretion in the appendix with which the author was before unfamiliar, and that it may open up adjacent small intestine without the formation of an abscess. The fifth case shows almost the same course of events, in which an appendix inflamed, but without any concretion, and nearly ulcerated into the colon. Other cases illustrate the dangers from adhesions following inflammation of the appendix.

The Use of Borax and Formaldehyde as Preservatives of Food.—W. D. Halliburton urges that the use of foreign substances as preservatives of food be replaced by the more wholesale use of cold transportation and storage on the grounds that: (1) An antiseptic is inimical to the life of the organisms that cause putrefaction; it cannot, therefore, be harmless to the vital processes in the higher animals. (2) Numerous clinical observations have been recorded which show that dyspeptic and other troubles follow the use of foods which have been treated with commonly employed preservatives like borax. (3) Even if, as in the case of boric acid and borax, the poison is not cumulative, the continuous passage of foreign substances through the kidney cannot be beneficial to those organs. He has conducted experiments with artificial digestive mixtures to test the action of borax and formaldehyde, these being the preservatives usually employed. The tests are given at some length. These experiments appear to the author to prove conclusively the injurious effect produced by even minute quantities of certain preservatives on the activity of the enzymes concerned in ordinary digestion, and to furnish a cogent reason why the use of these substances should be prohibited for the preservation of food materials.

Two Cases of Concealed Accidental Hemorrhage.—A. E. Larking finds concealed hemorrhage more rare and fatal than placenta prævia. In both cases reported there was absence of hemorrhage from the vagina, and the amniotic fluid was so scanty that very little effect would have resulted from rupture of the membranes. The uterine contractions were sufficient to stop the hemorrhage. In the second case there was sudden death in convulsion. Few of the symptoms, such as loss of sight, noises in the head, hallucinations, sighing respiration, and imperceptible pulse, were present in this case.

The Nature and Treatment of Puerperal Infection.—T. E. Mitchell says some of the worst cases of puerperal fever he has seen have occurred after perfectly natural labor, when no digital examination or manipulation at all had taken place. Some cases originate in the impossibility of inducing many working-class patients to observe the ordinary rules of post-partum cleanliness. Quinine should be given in large doses in septicæmia (gr. xii.) as an initial dose. Vaginal douches and exploration of the uterine cavity for retained secundines are also recommended.

A Combined Recto-Vaginal Opening in the Human Subject.—J. G. Modlin relates a case in which on separating the vulva a movable septum was seen formed by the posterior vaginal and anterior rectal walls. The appearance was that of the muzzle of a double-barrelled gun. The steps of an operation for relief of the condition are given. It was successful, and defecation, previously causing very great pain and always hemorrhage, was rendered more natural.

A Large Multilocular Ovarian Tumor.—F. A. Baldwin gives with illustrations the history of a tumor which caused death without operation, and which was found to consist of several cysts, in all weighing one hundred and fifty-eight and one-half pounds, and containing eighteen gallons of fluid.

Conjunctival Diphtheria.—H. E. Smith tells of a case in which the diagnosis was suspected and at once confirmed. Such cases may readily pass unnoticed and infection be spread without the original source being recognized.

On the Confusion of Two Different Diseases under the Name of Rubella (Rose-Rash).—C. F. Dukes says that all authorities admit without reservation that there is one disease known as scarlet fever, a second as measles, and a third as rubella (German measles). He has recently observed a series of cases which leads him to believe that under the symptom-complex of the latter disease as at present regarded, there are really included two distinct affections. The second he speaks of as the "fourth disease." From his study of the series alluded to he claims for this "fourth disease": (1) that although its resemblance is so close to scarlet fever in many features, it cannot possess any affinity with that disease inasmuch as both diseases occurred concurrently in the same epidemic; (2) that some of the sufferers had both diseases in the same epidemic; (3) that one patient had scarlet fever followed by the "fourth disease"; (4) that several had the "fourth disease" followed by scarlet fever; (5) that although the "fourth disease" has been confused with rose-rash and regarded as a mere variety of rubella, this conclusion is fallacious, since nearly one-half the cases in an epidemic had already had rose-rash within a year or two, which, according to Cullen's established law, is incredible. He purposely refrains from attaching a name to the disease in order to avoid the anomalous description of the same disease under an indefinite number of terms, as in the case of its ally, which has been variously designated as "rubeola notha," "rötheln," "rubella," "German measles," "epidemic roseola," and "rose-rash." The distinguishing features of rubella, of the "fourth disease," and of scarlet fever are found in the tables appended.

Case of Pancreatic Diabetes due to Calculi.—E. W. Phillips records the case of a man aged fifty-one years, who when first seen was passing blood in defecation, had a rectal discharge which stained his clothing, and was much weakened and emaciated. The urine contained sugar; specific gravity 1.024; no albumin; five pints were passed in twenty-four hours. He died some seven months later. Autopsy showed that the pancreas was hard and its duct was filled with calculi and calcareous matter. The largest mass was situated in the head of the pancreas and was tubular in shape; the next largest was at the splenic end; a third could be felt in the posterior part of the head; the entrance of every branch duct was plugged with concretions. No communication could be found between the pancreatic and common duct or with the duodenum. The substance of the gland was hard but it was not enlarged. It was examined by the Clinical Research Association, and the report was as follows: "The pancreas shows great increase of fibrous tissue in parts with atrophy of acini and glandular tubules. A section of moderately large duct shows much shed epithelium from catarrh." The colors of the calculi and débris were chiefly yellowish-white and dark gray mixed.

On Immunity against Proteids.—W. Myers experimented on rabbits, using crystallized egg-albumen from the white of fowl's egg, serum-globulin from sheep, serum-globulin from the bullock, and Witte's "peptone." The results of the experiments cannot be given here in detail. It may be noted that with the peptone, strong support is given to the view that the production of immunity is due to processes of assimilation, and they also explain a physiological point which has long been a subject of discussion. When injected into the circulation peptone disappears very quickly from the blood-stream. Practically nothing is known as to the fate of the peptone which thus vanishes. But clearly this disappearance of peptone is exactly paralleled by the disappearance of the tetanus toxin from the blood-stream. In both cases we produce by immunization a specific anti-substance.

A Note on the Results Obtained by the Anti-Typhoid Inoculations in the Beleaguered Garrison at Ladysmith.—From statistical tables, A. E. Wright shows that the proportion, on the one hand of attacks, and on the other hand of deaths, from typhoid fever was seven times smaller in the inoculated than in the uninoculated. And it may be borne in mind that if the number (no doubt a considerable one) of men who had previously suffered from typhoid fever had been subtracted from the number of the uninoculated, as might quite legitimately have been done, the statistics would have borne an even more favorable aspect.

Münchener medicinische Wochenschrift, July 3, 1900.

The Atropine Treatment of Intestinal Obstruction.—Batsch strongly advises the use of atropiue in large doses (gr. $\frac{1}{2}$ hypodermically) in all cases of intestinal obstruction before deciding on laparotomy. The atropine treatmeut is to be persisted in as long as the patieut's life is not in immediate danger, but careful supervision is necessary lest operation he deferred till the prognosis has become hopeless. In illustration three cases are cited, two of which were relieved by the drug alone, while in the third the abdomen was opened and recovery followed the section of a strangulating adhesion.

The Demonstration of Bile Pigment in the Urine in Cardiac Diseases.—Ott comments on the yellow discoloration of the skin often accompanying chronic cases of heart disease, and gives a series of twelve in which bile pigment was found in the urine by the Huppert-Salkowski test, proving that it is a true jauudice. It is of importance to note that Gmelin's reaction gave a negative result in every one of these cases, and furthermore that even the more delicate test employed fails in the presence of notable quantities of blood pigment or albumin.

Venesection in Heat Prostration.—Klein relates the case of a stoker on a transatlantic liner who suddenly collapsed owing to the extreme heat, and was brought on deck unconscious and in a state of most violent convulsions. All the other available therapeutic measures having failed, and the patient being apparently about to succumb to respiratory and cardiac paralysis, venesection was tried as a last resort. About eight ounces of blood was allowed to flow, with instantaneous relief of the symptoms and subsequent recovery.

A Severe Case of Uræmia Cured by Venesection.—Hoesslin succeeded in saving the life of a uræmic patient *in extremis* by removing thirteen ounces of blood from the circulation. The attempt was not made until every other means of stimulation had been resorted to without avail, but the good effects of the operation were speedily apparent, and under digitalis the patient made an uucomplicated recovery.

A Contribution to the Study of the Cytolytic Sera.—Schütze considers that the property exhibited by the blood serum of certain animals, of causing the destruction of the blood cells of other animals when brought into contact with these either in the circulation or in the test tube, is due to the presence

of two substances. One of these, the 'intermediate body," possesses an equal affinity for the cellular elements, and the second, or "end body," and by acting as a sort of go-between enables the latter to produce its effect on the cells in question. It has been found possible to produce sera which have a cytolytic action on cells other than those of the blood (*e.g.*, the ciliated tracheal epithelium of the ox), and the hope is advanced that it may perhaps be feasible to manufacture a substance which shall exert this effect on the cellular components of malignant new growths. Working toward this objective point the author has made a number of experiments on rabbits and guinea-pigs, and sums up his results as follows: (1) The serum of normal guinea-pigs after having been subjected to repeated injections of hæmolytic rabbit's blood acquires an antihæmolytic property, *i.e.*, the ability to check or prevent the destruction of the blood cells of guinea-pigs. (2) The production of the antihæmolytic serum depends entirely on the presence of the "intermediate body," the "end body" taking no part in this action. (3) It has not yet been possible to produce an emulsion of normal guinea-pig organs (liver or kidney) which should exhibit properties similar to the hæmolytic rabbit serum, and be able to affect the cellular elements of the organs with which they have already been treated.

Subphrenic Abscess Resulting from a Traumatic Suppuration of the Pancreas.—Strohmayer relates the case of a middle-aged laborer who, after suffering for a month from indefinite symptoms accompanied by great cachexia and general debility, suddenly had an attack of extreme dyspnœa and died in collapse. The autopsy revealed an extensive subphrenic abscess which had perforated the diaphragm on the right side and discharged a great amount of pus into the pleural cavity. The abscess antrum also communicated with a suppurating focus surrounding the head of the pancreas, which seemed to be its place of origin. The only explanation of the cause of the lesion seemed to be a severe blow received in the epigastrium three months before. This is supposed to have produced contusion and hemorrhage of the pancreas, the damaged area later being invaded by intestinal germs and suppurating.

Enucleatio Bulbi, its Substitutes, and a Consideration of Sympathetic Ophthalmia.—By Schmidt-Rimpler.

Experience with a Morphine Substitute.—By L. Nied.

My Experience with Photo-Therapy.—By Strebel.

Berliner klinische Wochenschrift, July 2, 1900.

Is the Increase of Blood Cells in High Altitudes an Apparent One or Not?—A. Gottstein and G. Schrader discuss this question in the light of comparisons made of the same specimen of blood at different altitudes. They consider the instrument in which the chamber containing the portion of blood to be examined is a slit-shaped cavity, a more reliable one than the Thoma-Zeiss instrument, which has for so long a time been employed for this purpose. They find that the higher the altitude the greater the number of corpuscles seems to be. The same specimen will present variations, the cell count increasing as the altitude rises. This is the case with the Thoma-Zeiss instrument, but this variation does not obtain with the slit instrument. From these results the authors conclude that the former is liable to error dependent on the atmospheric pressure, which at the lower level exerts a greater force on the fluid layer in the chamber and so forces out a certain number of cells which are not so influenced by the lighter pressure at the higher altitude.

A Contribution to the Therapeutics of Aspirin.—P. Zimmermann has used this remedy in some thirty cases of rheumatism, neuralgia, exudative pleurisy, and renal inflammation. The daily dosage ranged from 2.5 gm. to 4 gm. It was well borne by all the patients, generally acting as a powerful diaphoretic and causing a fall of temperature. It answered well in certain rheumatic cases in which the salicylates were not well borne. It did not depress the heart, and the presence of valvular incompetency did not seem to be any contraindication to its employment. Some benefit was also obtained in chronic rheumatism. It was used for its diuretic effect in pleurisy and renal disease. It acted well in the former but failed in the latter. Zimmermann considers it a valuable addition to the list of agents to be given in rheumatic states.

The Composition of Renal Calculi.—L. Spiegel gives the analyses of fifty-five cases. In fourteen of these the main ingredient was calcium oxalate, and in a like number calcium phosphate. Nothing can be learned from the peculiarities of the urine in a given case as to the probable composition of the calculus, except that he has found that in cases in which the oxalate is the essential ingredient there is more apt to be a continuous acid reaction.

Some Pyrexias of Hot Countries.—E. Legrain gives notes upon the fevers of hot climates and the influence exerted upon them by quinine. The two great classes are intermittents and febrile affections not corresponding to the various types of malaria. The study is based on three hundred cases. He finds it possible from a single access to determine the type of intermittent. A number of conclusions are drawn as to the changes in type, the only stable type being the quartan. Intermittent fever gives no mortality. It can be arrested at will for a determined period by means of a single dose of quinine appropriate to each case. No other exotic pyrexia reacts in the same manner in respect to quinine.—*La Presse Médicale*, July 7, 1900.

Intestinal Syphilis.—Professor Fournier looks upon specific affections of the intestines almost as curiosities, having observed in all not more than a dozen instances. Diarrhœas of tertiary syphilis seem quite frequently to recur at longer or shorter intervals. They may also occur quite late; he has seen them in persons whose infection dated back from nineteen to forty years. Greater confidence is placed in mercury than in the iodides; still, mixed treatment does well, although protoiodide pills or Van Swieten's solution will effect a cure. Inunctions or subcutaneous injections seem to constitute the treatment of choice.—*Journal des Praticiens*, July 14, 1900.

Diagnosis and Treatment of Cutaneous Actinomycosis.—Lenoir and Claisse report the case of a butcher who frequented abattoirs where infection was made possible. The first signs were in the floor of the mouth in the form of a pseudo-ranula; afterward swelling of the cheek showed characteristic yellowish discharge and granules. Although iodide of potassium is almost a specific, treatment is protracted. Six months were required to bring about decided improvement under as large doses as could be tolerated.—*Journal des Praticiens*, July 14, 1900.

Achondroplasia.—Pierre Marie gives an exhaustive account of this defect of development of the human skeleton in adolescence and adult age. The article is freely illustrated and supplied with a bibliography of cases reported above the age of ten years. It must be admitted that the affection may be of hereditary origin. It remains for future investigators to show whether the lesion of the cartilage is primordial or a dystrophy of general cause. At present facts are lacking for a decision of this question.—*La Presse Médicale*, July 14, 1900.

The Edinburgh Medical Journal, July, 1900.

The Morbific Agent and the Reparative Effort.—Andrew H. Smith, of New York, asks if it would not be a gain to both pathology and practice if a direct interaction between the morbific agent (noxa) and the reparative effort were recognized, the conception of an intermediate so-called inflammatory process being abandoned. He thinks the conception of inflammation as an active process is erroneous and unfortunate in its influence upon medicine. The noxa, he says, may be active, the tissues may be active, but the inflammation never. "It is simply a name, not a force. It can do nothing. The collision of two armies is called a battle, but the battle is not an entity apart from the armies. Much less can it join forces with one of them and help on the fight against the other. Yet this is what inflammation is supposed to do when it is credited at one time with opposing the noxa and helping forward the reparative effort, and at another time with attacking and destroying the tissues." Furthermore, the energy that initiates the "inflammation" is the energy that maintains it, and if we withdraw this energy, the noxa, the "inflammation" will cease. Medical science has too long rested under the incubus of this name, and the author urges that the entire doctrine of "inflammation" be abandoned, and that the phenomena ascribed to this process be assigned to new relations, in accordance with recent advances in pathology, and especially in bacteriology—advances that have rendered obsolete a conception handed down to us from remote ages. In the matter of nomenclature, this proposal would involve doing away with the termination "itis." As most of the phenomena heretofore included under the term "inflammation" are manifestations of the

local action excited by a micro-organism, or by a poison circulating in the blood, such action may be expressed by a termination affixed to the name of the organism or poison, if the same can be determined, or to the organ or part affected, in case the particular infecting organism or poison is not identified. We have a universally accepted precedent for the first-named use in the case of *tuberculosis*, and the use of this termination might be extended to the action of other organisms. Thus, *streptocosis* would express an infection by the streptococcus, *staphylocosis* an infection by the staphylococcus, *gonocosis* an infection by the gonococcus, and so on, a localizing adjective being used to denote the seat of the affection. Infection by an undetermined organism would be *microbiosis*, or *bacteriosis* as a general term, or it would be expressed by adding the termination to the name of the part in the same way as "itis" is now employed. Thus, *pericardosis* would denote simply infection of the pericardium; *pericardial pneumocosis*, infection of pericardium by pneumococci. We should have, also, *scarlatinosis* (renal, glandular), and *rheumatosis* (articular, endocardial), expressing the local action of a poison in the blood.

If a general term is still demanded as a substitute for "inflammation," it would be necessary to employ at least three words to express different kinds of noxæ, acting in different ways, and leading to essentially different results. These might be *traumosis*, to include wounds and injuries; *toxosis*, to include the local action of poisons in the blood; and *bacteriosis*, to include the action of micro-organisms. But the matter, Dr. Smith says, is one of great practical importance, and not simply one of nomenclature. So long as inflammation presents itself before us as something to be combated, so long we are tempted to look away from the continuously acting morbific agent, and at the same time to ignore the effort that the tissues are making for their own defence and repair. In striking at the *ignis fatuus* of inflammation, we overlook our real enemy, and are liable to injure our friend. For example, if we treat the inflammation in a furuncle by application of cold, we may succeed for a time in diminishing the swelling, redness, heat, and pain, but the noxa in the form of bacteria will still be there, and we shall certainly have to deal with it in the end. If bacteria are at work in the appendix vermiformis, and we are very successful in combating the inflammation by our local and general treatment, we may succeed in preventing the effusion of lymph that would have walled in the infected area, and be rewarded by seeing our real enemy in possession of the entire field of the peritoneum.

Or, once more, if we have a multitude of colonies of pneumococci growing in the exudate which is occupying the air cells of a portion of lung, and we seek to control the inflammation by means of arterial sedatives, we may find a little later that we have only diminished the power so sorely needed to propel the blood through the obstructed lesser circulation, and added to the danger that our patient will succumb to failure of the right heart.

Finally, in doing away with the idea of inflammation we shall be on the road to a more exact diagnosis, for we should then be driven to discriminate in our language between conditions as unlike as sclerosis of the tympanum and hip-disease, or as ulcer of the cornea and diarrhœa. Then the use of a less exact designation would be a confession of failure to arrive at the more precise one.

Some Results of Antistreptococcus Serum.—F. J. Harvey Bateman prefaces a report of three cases with a consideration of the many difficulties in the way of arriving at definite conclusions with reference to the beneficial results of antistreptococcus serum. The first arises from uncertainty as to the number of varieties of streptococci. Then, in many cases the causation of the disease is complex, the origin often lying in a mixed infection. Still another reason for doubt as regards orrhotherapy in general is to be found in the frequent absence of any bacteriological proof of the nature of the infection. And finally there is the undeniable fact that many instances even of grave microbic infection undergo spontaneous recovery. This has been frequently the case as regards streptococcal disease, and the consideration must render many minds sceptical as to the beneficial effects of antistreptococcus serum. In two of the three cases reported it was definitely established that the disease was due to the presence of streptococci. In the first case the effect of the serum was early manifested, and the temperature, which had been fluctuating considerably, came to normal within ten days of the commencement of the administration of the serum. In the second case the serum was not employed until the patient had been under treatment for six weeks, and it was necessary to continue its employment for a considerably longer time. As regards the third case, although every means had been adopted in order to arrive at a correct diagnosis, the real cause of the disease remained obscure. The employment of antistreptococcic serum, therefore, in this instance was resorted to simply on the chance of the infection being due to streptococci, and it was not surprising that the results of treatment were unsatisfactory.

Persistence of the Arterial Duct and its Diagnosis.—G. A. Gibson reports a case of this condition, and from a study of it and of four other cases which have come under his care during the last few years he notes the following points upon which, he thinks, the diagnosis of persistent ductus arteriosus may be founded with perfect confidence. There may be no dyspnœa, cyanosis, œdema, or other evidence of disturbance of the general circulation, and the recognition of the lesion may depend entirely on the presence of a few physical signs. Inspection may fail to yield any facts of diagnostic importance; palpation usually reveals the long thrill following the apical impulse, and enduring beyond the recoil of the blood on the semilunar cusps, which may be felt during the thrill; percussion may not show any enlargement of the cardiac dulness; but auscultation gives convincing evidence of the lesion in a murmur which may be regarded as almost pathognomonic. Beginning distinctly after the first sound, it accompanies the latter part of that sound, occupies the short pause, accompanies the second sound, which may be accentuated in the pulmonary area, or may be, and often is, doubled, and finally dies away during the long pause.

Clinical Notes on Cases of Beriberi.—J. O. Affleck reports six cases of beriberi which have been under his care during the past five years at the Edinburgh Royal Infirmary. All these cases, except one, occurred in seafaring men, and all were in persons who had come from tropical or subtropical regions. Each case presented the characteristic features of a peripheral neuritis, and, in addition in most of them there was more or less œdema of the legs. The treatment included rest, the employment of sodium bromide and nux vomica, and a generous diet, under which the patients improved quite rapidly. In three cases a bacteriological examination of the blood was made, but with a negative result.

Acute Infantile Intussusception, with Special Reference to Treatment by Primary Laparotomy.—By W. Blair Bell.

Two Cases of Agoraphobia Cured by Hypnotic Suggestion.—By Charles Lloyd Tuckey.

The Therapeutics of Disorders of Menstruation.—By H. Macnaughton Jones.

A Case of Retroverted Gravid Uterus.—By G. R. Fraser.

Zeitsch. f. Diatet. u. Physik. Therapie, vol. iv., No. 3.

The Assimilative Processes in Chronic Rheumatism.—While Weisz considers that the attempt to formulate a specific diet as being necessary or indicated in chronic rheumatism is far-fetched, he believes that the question of feeding is of great importance and may be made a valuable therapeutic aid. In general he groups the cases into those suffering from obesity and those whose weight is steadily decreasing. In the first class the most important indication is to cure the joint disease itself, though the various obesity cures may be of service in seconding the process. Very much more frequent are cases exhibiting various degrees of emaciation. In these what is essentially a stuffing process must be resorted to, and the patients encouraged to consume as much food of all sorts as possible.

The Therapeutic Application of Natural Animal Gastric Juice.—Mayer discusses the theoretical considerations which justify the supposition that the gastric juice of dogs would be of value in treating achylia in man, and then describes the Pawlow-Shumow-Simanowski operation by means of which large quantities of secretion may be obtained from the animals. Experiments with this agent have already been made in France, where it is known and commended under the name of "gastérine." The author's clinical observation is limited to one case, but in this the results were encouraging, and he advises further experimentation.

The Treatment of Vesical Neuroses.—Auerbach thinks that properly executed massage and gymnasties are of great value in the treatment of irritable bladder not due to organic lesion. The manipulations and movements are described in detail and have for their object the improvement of the nervous and muscular tone of the pelvic contents.

A Comment on Professor A. Poehl's Dissertation on "The Osmotic Pressure of the Body Fluids in its Relation to the Origin and Persistence of Morbid Processes."—By Korányi.

The Influence of the Newer Food Preparations on the Intensity of Intestinal Decomposition.—By Lewin.

An Experimental Contribution to the Dietetics of Hyper- and Hypochlorhydria.—By Buch.

Massage Baths.—By Preiss.

Reviews and Notices.

A Manual of Operative Surgery. By Lewis A. Stimson, M.D., Surgeon to the New York and Hudson Street Hospitals, etc., and John Rogers, M.D., Surgeon of Gouverneur Hospital, etc. Fourth and revised edition. Illustrated. Philadelphia: Lea Brothers & Co. 1900.

It is hardly necessary to do more than to record the appearance of another edltion of this work, which already is very favorably known. This edition is improved by some condensation and the elimination of a number of obsolete illustrations, and in its present form is an excellent handbook of the subject. The descriptions of operations are terse and to the point, but in some departments the necessary entailment has interfered with completeness, so that the book can hardly be used as a work of reference. The illustrations are very satisfactory, and the general appearance and make-up of the book are excellent.

Medical and Surgical Report of the Presbyterian Hospital in the City of New York. Vol. IV., 1900. Edited by Andrew J. McCosh, M.D., and W. Gilman Thompson, M.D. New York: Trow Directory Printing and Bookbinding Company. Pp. 223.

This neat little volume contains many interesting articles on various medical and surgical subjects as noted in the wards of the hospital. Among them may be mentioned: The Surgical Treatment of Ascites due to Cirrhosis of the Liver; A Case of Dermatitis Exfoliativa; Remarks on the Surgery of the Biliary Passages; A Contribution to the Surgery of the Testicle; Report of Ten Cases of Subphrenic Abscess; Empyema; Report of Twenty-eight Cases of Suppurative Hepatitis; Statistics of One Hundred Cases of Cancer of the Breast; Heart Murmurs and Heart Lesions, and many other interesting articles.

The Cell in Development and Inheritance. By Edmund B. Wilson, Ph.D., Professor of Zoology, Columbia University. Second edition, revised and enlarged. New York: The Macmillan Company. London: Macmillan & Co., Limited. 1900. Pp. 483.

Although the author states that he has not covered the whole subject of cytology, he is to be congratulated in the very efficient manner in which he has managed his selections and discarded the non-essential, although interesting matter. His work is a model of conciseness without lacking clearness. The theories, experiments, and data are all presented in a most interesting way, and the scientific standard attained is very high. This edition differs from its predecessor chiefly in being brought up to the times, in its being enlarged, and in the addition of fifty or more illustrations. For medical men who are willing to depart from the more directly practical studies of their profession this work will prove extremely interesting. The bibliography and indexing are worthy of the highest praise, while the glossary makes the work more easily handled by those not thoroughly conversant with the technical terms of the biologist.

Forty Years in the Medical Profession—1858–1898. By John Janvier Black, M.D., Member of the College of Physicians of Philadelphia; Member of the Delaware State Medical Society, etc. Philadelphia: J. B. Lippincott Company. 1900. Pp. 498.

Dr. Black has given us a most pleasant account of his impressions as a medical man, his thoughts on the causation and theories of disease, the different methods of treatment, and how the changes have taken place during the last forty years, in all of which time he has been active as a general practitioner not only in doing his simpler duties as a physician, but also philosophizing upon all he saw. The book is written for his professional brethren, and to them it cannot fail to appeal as most interesting and instructive, for the author has let no important advance in his art escape him, and his long service therein seems to have added zest to his work rather than to have tired him.

Chemistry and Physics: A Manual for Students and Practitioners. By Walton Martin, Ph.B., M.D., Assistant Demonstrator of Anatomy College of Physicians and Surgeons, New York, and William H. Rockwell, Jr., M.D., Assistant Demonstrator of Anatomy College of Physicians and Surgeons, New York. Edited by Bernard B. Gallaudet, M.D., Demonstrator of Anatomy and Instructor in Surgery, College of Physicians and Surgeons, New York; Visiting Surgeon Bellevue Hospital, New York. Illustrated with 137 engravings. Philadelphia and New York: Lea Brothers & Co. Pp. 374.

The authors have succeeded in giving a very satisfactory synopsis of the subjects treated, with a special view to the book's adaptability to medical students. It is not intended as a work for physicists and chemists, but merely as an introduction to knowledge which it is necessary for the practitioner to apprehend at least, and as such contains enough and even more than enough for all practical purposes.

Diseases of the Eye. By Edward Nettleship, F.R.C.S., Ophthalmic Surgeon at St. Thomas' Hospital, London; Surgeon to the Royal London (Moorfields) Ophthalmic Hospital. Revised and edited by William Campbell Posey, A.B., M.D., Ophthalmic Surgeon to the Howard and Epileptic Hospitals, Philadelphia; Assistant Surgeon, Will's Eye Hospital; Fellow of the College of Physicians of Philadelphia; Associate Member of the American Ophthalmological Society, etc. Sixth American from Sixth English edition. With a Supplement on Examinations for Color-Blindness and Acuity of Vision and Hearing, by William Thomson, M.D., Emeritus Professor of Ophthalmology in the Jefferson Medical College of Philadelphia. With 5 colored plates and 192 engravings. Philadelphia and New York: Lea Brothers & Co. 1900. Pp. 560.

This well-known text-book again appears in its sixth edition in a form adapted to American readers by an American editor. Although the book has been thoroughly revised, the text has been altered as little as was consistent with the recent advances made in the knowledge of the subjects treated. The appendix is supplied with full details regarding the examination of applicants for army, navy, and merchant marine of the United States, and formulæ, test types, etc. The popularity of the work is bound to be sustained by this new and improved edition.

The Annual of Eclectic Medicine and Surgery (1897–1898). Vol. VIII. Edited by John V. Stevens, M.D., Professor of Diseases of the Nervous System in Bennett Medical College, Chicago. Cincinnati, Ohio: The Scudder Bros. Company.

This is a report of papers and proceedings from the States having eclectic societies. The volume was somewhat delayed in publication. There are 507 pages exclusive of index, well bound and containing full-page portrait illustrations of physicians from different sections. The frontispiece is a portrait of Dr. Buchanan, who died in 1899. The papers are for the most part brief.

Transactions of the Luzerne County Medical Society.

This is Vol. VII. of the society's reports, but nothing shows in what State Luzerne County is located. On page 180 the number of deaths in Wilkes-Barre is given, so it is presumably Pennsylvania. There are a number of good papers and a picture of cancrum oris.

Membership Directory of National Medical Societies of the United States. New York: E. R. Trott. 1900.

This book contains the names and addresses of officers and members of the nineteen national associations. An index to the whole makes the search for a given name easy. The directory will be of value to the layman as a mailing-list or when looking for an eminent specialist or consultant. Yearly editions will be necessary.

Untersuchungen ueber die Moeller Barlow'sche Krankheit. Von Dr. J. Schoedel und Prof. C. Nauwerck. Jena: Verlag von Gustav Fischer. 1900.

The authors here present in a brochure of one hundred and sixty pages the individual work of Moeller, Barlow, and others referred to in a bibliography containing one hundred and thirty-nine items. The pathological anatomy of the affection is carefully studied, and the authors present five personal cases with history, comments, and conclusions. The question is presented in as well elaborated a report as one could desire, and will undoubtedly be read with interest by all engaged in practice among children.

Traité de Médecine. Publié sous la direction de MM. Bouchard, Professeur à la Faculté de Médecine de Paris, Membre de l'Institut, et Brissaud, Professeur à la Faculté de Médecine de Paris, Médecin de l'Hôpital Saint Antoine. Deuxième Édition. Tome IV. Paris: Masson et Cie. 1900.

The fourth volume of the second edition of this excellent system of medicine is devoted to diseases of the mouth, pharynx, stomach, pancreas, intestine, and peritoneum. The diseases of the mouth and pharynx are treated of very satisfactorily by Dr. A. Ruault in an article of some one hundred and fifty pages. About half the volume is taken up by a complete treatise on diseases of the stomach by Dr. A. Mathieu, who is also the author of the article on diseases of the pancreas in the same volume. The third contributor is Dr. Courtois-Suffit, who writes on diseases

of the intestine and peritoneum. The volume is a notable addition to the rapidly increasing literature of diseases of the digestive tract.

Ricerche sulla Presenza della Zucchero nelle Orine delle Donne Gravide e Puerpere. Par Dottor Giuseppe Cristalli. Napoli: Tipografia Forense Commerciale. 1900.

In this monograph Dr. Cristalli studies the question of glycosuria in pregnancy and the puerperium, and records the results of a number of personal observations. He distinguishes carefully between lactosuria and glycosuria, the former being an almost constant condition in the puerperal period, while the latter is, though not very rare, much less frequent than lactosuria. The one is of no pathological importance whatever, the other of a much more serious nature.

The Pathology and Surgical Treatment of Tumors. By N. Senn, M.D., Ph.D., LL.D. Second edition, 718 pages, illustrated. W. B. Saunders, Philadelphia. 1900.

The second edition of this book is as admirable as the first. The work has been revised; an additional chapter on sarcoma of the decidua has been added, together with many new excellent illustrations. The author still adheres to the Cohnheim hypothesis concerning the origin of tumors, and rightly considers as unproven the causative relation between bacteria and the growth of carcinoma.

Transactions of the American Dermatological Association, Twenty-third Annual Meeting, Philadelphia, May 30 to June 1, 1899. Official report of proceedings, by George Thomas Jackson, M.D., Secretary. Paper, 176 pages. The Rumford Press, Concord, N. H. 1900.

There are fewer good illustrations in this than in several of the society's recent reports, but aside from this the volume compares fairly well. The quality of the papers is of the usual rather high order. If the printer would put the title of the various papers at the head of the page instead of monotonously repeating "Amer. Derm. Assn.," it would materially aid the reader and increase the attractiveness of the reports.

Progressive Medicine, Vol. I., 1900. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in Jefferson Medical College of Philadelphia. Octavo, bound in cloth, 404 pages, 36 engravings and a colored plate. Lea Brothers & Co., Philadelphia and New York. Issued quarterly.

The author has been assisted in his work by Charles A. Holder, of the Jefferson School. There are presented in this volume the surgery of the head, neck, and chest, infectious diseases, including acute rheumatism, croupous pneumonia and influenza, diseases of children, pathology, laryngology, rhinology, and otology. The contributors are Da Costa, Packard, Blackader, Hektoen, Turner, and Randolph. There is an excellent colored plate in illustration of Koplik's spots, and points of interest are to be found in each department. As a year-book the defect stands out that so few branches are covered in each quarterly issue.

Le Lesioni Traumatiche dei Centri Nervosi. Par Dott. Salvatore Salinari. Roma: Il Giornale Medico del Regio Exercito. 1900.

This is a treatise of three hundred and twenty pages on injuries of the brain and spinal cord and their meninges, which was the Riberi prize essay for 1898. The author is a surgeon-captain in the Italian army, and naturally devotes a large part of his work to gunshot wounds and their treatment in the field.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by Thomas L. Stedman, M.D., New York City. In twenty volumes. Vol. XIX., "Malaria and Micro-Organisms." New York: William Wood & Company. 1900.

To this important volume there are but four contributors. Their names, however, carry a conviction of their ability to give in the eight hundred pages covered by their contributions all that is at present known of these most interesting topics. There are eleven beautifully executed plates on heavy glazed paper, which serve as frontispiece illustrations of the article on Malaria by Ettore Marchiafava and Amico Bignami of Rome. This in itself makes a book of over five hundred and twenty pages, going into every phase of the question to which of late so much interest has attached. Simon Flexner, of Philadelphia, contributes the greater portion of the text on Micro-organisms, dealing first with the history and technique of bacteriology, then considering at length bacilli and cocci and other forms. Eugene L. Opie, of the Johns Hopkins University, follows with Protozoa, arranged according to classes and orders; the whole subject is made as concise and clear as is consistent with scientific accuracy. As a whole, the work is one of great interest, and the part played by the mosquito in transmitting malaria, now attracting such general interest, is found here freely discussed.

Diseases of the Genito-Urinary System: A Thorough Treatise on Urinary and Sexual Surgery. By Eugene Fuller, M.D., Professor of Genito-Urinary and Venereal Diseases in the New York Post-Graduate Medical School, etc. New York: The Macmillan Company. 1900.

The author finds that most recent works on genito-urinary affections have been written from a purely venereal or dermatological standpoint, or the special articles relating to the kidneys and bladder in works by many writers have been prepared by general surgeons rather than by those professing special skill in genito-urinary affections. He finds the attempts made by venereal specialists to write on surgical topics usually disappointing. The author has therefore sought to avoid the shortcomings enumerated, and has written from the purely surgical standpoint, giving his individual views and methods freely. Whether the term "thorough" in the title will stand an exacting test is questionable.

Traité de Médecine et de Thérapeutique. Publié sous la direction de MM. P. Brouardel et A. Gilbert. Tome septième: Maladies du Nez, du Larynx, de la Trachée, des Bronches, et des Poumons. Paris: J. B. Baillière et Fils. 1900.

In the list of contributors to the present volume we note the names of Cartaz, Castex, Barbier, H. Barth, P. Claisse, Mosny, L. Landouzy, H. Triboulet, Grancher, Balzer, Méry, and Le Noir. In such a treatise not much that is new can be looked for. Suffice it to say that the various articles display an acquaintance on the part of their respective authors with the most recent advances in diseases of the air tract, and can be accepted as representative views of the present-day school of clinical teachers in France.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE BARTHOLOMEW HOSPITAL SITE—THE CHARGE AGAINST THE WAR HOSPITALS—COMMISSION PROPOSED IN PARLIAMENT AND ADDED TO—CONAN DOYLE ON THE STATE OF BLOEMFONTEIN—KNIGHTHOOD—SUNDAY FUND—DEATH OF PROFESSOR D. J. LEECH—COLLEGE OF SURGEONS ELECTIONS.

London, July 6, 1900.

On Monday the Prince of Wales presided at a special court of the governors of St. Bartholomew's Hospital. The report of the almoners and treasurer gave the story of futile negotiations for the purchase of part of the site of Christ's Hospital, now removed to the country. In December, 1893, the governors of the latter agreed to sell an acre and a half of the land to St. Bartholomew's at a price to be fixed by arbitration, but up to this time it has been impossible to get them to fulfil their agreement. To end the deadlock a sum of £117,000 has been offered and declined, and it was moved that if this be not accepted the aid of Parliament be sought. The Prince expressed deep regret that Christ's Hospital had not thought fit to stick to their engagement, and "the scanty courtesy, to say the least of it, with which they have treated us." He trusted that the charity commissioners would back up the claim of St. Bartholomew's, and that Parliament would not refuse what is for its benefit. The resolution was carried unanimously.

Medical questions have been forced into the background by the general news of danger and death in all directions from China to New York, where the terrible catastrophe from fire opened the week with a thrill of horror which penetrated to the remotest telegraph station.

One medical question has, however, made itself heard, but chiefly because it is far more than a medical—it is a national question. Is the army medical service a failure? Are the statements of Mr. Burdett-Coutts, which I mentioned in my last, true in substance? The committee suggested by Lord Roberts and accepted by the government will have the responsibility of investigating and pronouncing upon the charges against our war hospitals. Meanwhile the newspapers are flooded with correspond-

ence and interviews. Of course very opposite views are expressed. Sir W. Thompson and Mr. Conan Doyle and other able surgeons at the front repudiate any charge of neglect or incapacity of the medical staff as distinctly as Sir W. MacCormac and Mr. Treves have done. Here it is right to say that Mr. Coutts indignantly repudiates the idea that he has attacked Lord Roberts or any officer whatever, or the personnel of the Royal Army Medical Corps. As to the latter, he agrees with all observers that they have nobly done their duty under great difficulties, and some at the cost of their lives. *The Times*, too, has written in the same sense.

The proposal of Lord Roberts to send out a small commission to inquire—"one or two medical men and some man of common-sense"—having been accepted by the government, the names of the proposed commission were submitted to the House of Commons last night. They were Dr. Church, president of the Royal College of Physicians of London; Professor Cunningham, of Dublin; and Lord Justice Romer. No sooner had Mr. Balfour stated the names than Mr. Labouchere moved the adjournment of the House in order to denounce the composition of the commission. The presence of two doctors to inquire into charges against doctors and the medical service he vehemently opposed. He was seconded by Mr. Burdett-Coutts, who thus largely discounted his profession that he did not blame the department. Mr. Balfour pointed out that the medical men proposed had no connection with the army, but the feeling of the House had been excited and it was obvious a larger commission would be preferred. Therefore, though against his own judgment, he agreed to add two members.

At the meeting of the cabinet to-day it is supposed the subject of the war hospitals will be considered. There is some fear that one, if not two, of the proposed gentlemen may decline to act in consequence of the remarks made in the debate. I hope they will not withdraw, but will consider how exciting were the charges made by Mr. Coutts, and how the tension in the House only reflected that outside. The question is not one for party—it is a national one.

Mr. Conan Doyle has sent home a letter from which extracts appear in the newspapers to-day, and which is a valuable contribution to the evidence, inasmuch as it was written at Bloemfontein before the charges of Mr. Coutts were made, being dated the 5th of June. In this letter he points out the crisis caused by the terrible epidemic of typhoid, and says that, being confronted with a task demanding four times more men than the department had, the only way to meet it was for the men to work four times as hard. "This is exactly what occurred and the crisis was met. In some of the hospitals orderlies were on duty for thirty-six hours in forty-eight." Then he tells how these orderlies, "not picturesque figures, are patriots facing danger twelve hours of the twenty-four, just as real and far more repulsive than the scout or the gunner." Further, anticipating the adverse criticism likely to be made after the war, he says the captious may quote cases of overcrowding or hardships, and asks, "How can it be otherwise when a department sufficient for two army corps has to provide for the wants of two hundred thousand men with typhoid raging among them?"

Conan Doyle will be read by the great public, and his words weighed against those of sensational correspondents. He, like every reasonable man, wishes the truth and the whole truth to be known—even if the War Office should have to be sacrificed with all its red tape. If any one is to blame, let him be called to account; but no one department can bear the burden of the War Office's shortcomings.

Dr. Hector Cameron, of Glasgow, and Dr. Philipson, of Newcastle-on-Tyne, have been knighted.

Surgeon-General Jameson and Sir William MacCormac have received honorary degrees from Dublin University.

The Hospital-Sunday fund has reached at present only about £31,000, so that there is certain to be disappointment to the optimists. One church, at Lancaster Gate, made the largest collection ever received for the fund by a single congregation—the amount being £1,519.

I regret to announce the death of Dr. Leech, professor of materia medica at Owens College, on the 2d inst., in his sixty-first year. He was well known in London, and his work will be known to you. In Manchester he is mourned as a distinguished citizen, always ready to help the advance of education, the public health, and general progress. He had filled most of the chief offices in the Victoria University, and for some time represented it in the General Medical Council. For some years he edited the *Medical Chronicle*. You will remember his Croonian lectures in 1893 on the nitrites and allied compounds.

Mr. A. Cooper and Mr. Tweedy were yesterday re-elected to the council of the Royal College of Surgeons. Dr. Ward Cousins and Mr. Pearce Gould were chosen to fill the other vacancies. There were twelve candidates for the four vacancies.

Clinical Department.

HÆMOPHILIA IN THE NEGRO

By LOUIS BUCK, M.D.,

PORTLAND, ORE.

I WISH to add to literature two more cases of hæmophilia in the negro, one that of a man aged thirty years, the other that of a woman aged twenty-four years. In the latter (which was the second attack she had) plugging of the nares was kept up for three days, but when the plug was removed hemorrhage recommenced. Then plugging was again resorted to for four days more, which had the desired effect.

In the former case suprarenal extract with plugging was tried with but temporary success, the hemorrhage returning in three hours. The same procedure was again performed, with the same results. Then I administered internally gr. x. calcium chloride in solution every three hours, combined with anterior and posterior plugging of the nares, when I had no further trouble.

EXTRAVASATION OF URINE FOLLOWING STRICTURE OF LARGE CALIBRE.[1]

By JOSEPH E. BISSELL, M.D.,

NEW YORK.

THE following case illustrates a point easily overlooked at times. The fact that a stricture of moderate or even large calibre may remain unnoticed and still lead to disastrous results is worth recalling to your attention in a brief way.

The patient, J. Y——, forty-one years of age, was brought into the hospital on the afternoon of May 3, 1900, with a temperature of 105° F., pulse of 124. The history, as well as it could be obtained, is as follows: He had been ill three weeks. His illness began with a chill and rise of temperature. He has had, as far as we could learn, irregular chills since, with loss of appetite, occasional vomiting, pain in the abdomen; at times delirium. He complained principally of the pain all over the abdominal region. The bowels were somewhat loose. He was able to pass his urine at normal intervals in normal quantity, and without pain. He has had two attacks of urethritis, the last several years ago. He lives in a malarial district. He told the house physician that he had either malaria or typhoid fever, his doctor was not certain as yet which. On examination, the surface of the abdomen below the level of the umbilicus was found to be tender and boggy, extending into the left loin and into both groins, where it was reddened and at points fluctuated. The scrotum was swollen, discolored, and œdematous, and on the lower portion was a patch of gangrene the size of a trade dollar. The perineum was moderately swollen and there was a fluctuating swelling, most marked to the left of the median line. The perineal region was not especially tender, neither was the abdominal wall. He says his doctor had passed a catheter a few days before without trouble, and while in hospital he passed voluntarily without much pain or difficulty a pint of cloudy, bad-smelling urine. This being examined was found to contain some pus and albumin, and was of high specific gravity.

The man was at once taken to the operating-room. A 26 French sound was passed with a little difficulty into his bladder. It was obstructed slightly at about four and one-half inches, and a bougie à boule de-

[1] Read before the Medico-Surgical Society of New York City, Friday, May 18, 1900.

tected a decided contraction at this point of 24 and 25 mm. The sound was then replaced, an external urethrotomy performed, and this stricture divided; a tube, carried through the opening along the urethra into the bladder, brought out about a quart of ammoniacal urine. Just behind the perineo scrotal junction and to the left of the median line was a fluctuating tumor containing urine and pus, communicating with the urethra behind the stricture. A probe carried forward in its cavity went under the skin and superficial fascia of the groin and under the fascia of the abdomen in all directions, showing the undermining done by the urine escaping at this point from the urethral canal. The other tissues of the abdomen, the scrotum, perineum, and even into the lumbar region, were incised and drained. A tube was left in the bladder through the perineal wound. The patient's temperature and pulse within a few hours fell to nearly normal, and he appeared to be improving rapidly; but in about twenty-four hours after the operation he had a chill, his temperature and pulse rose rapidly, and he died septic inside of thirty-six hours from the time I first saw him. The infiltration had extended even into the tissues of the back from his left side.

The case is interesting because of the extensive extravasation, in spite of the fact that he was passing his urine at regular intervals, notwithstanding that an ordinary catheter passed into the bladder with little or no difficulty, and that there was no sudden or complete rupture at any part of the urethral canal. An indifferent or careless observer would thus be very easily misled as to the disease and its gravity.

Extravasation of urine following stricture of large calibre is not uncommon and is very easily explained. Following a chronic urethritis after a localized point of inflammation has set up a plastic exudation extending to the submucous structures, new connective tissue forms, and as a result becomes an obstruction in the canal. This obstruction need not be circumferential to accomplish its object. It is a dam in the way of the normal outlet. The urine is forced forward by pressure from the bladder and the deeper perineal muscles. The tissue immediately posterior to this hyperplastic spot, being softer, yields gradually. The epithelial protective layer is damaged, a tiny laceration; then slight ulceration occurs, infiltration of a more or less infective urine takes place, followed by a folliculitis, a periurethritis, and a follicular departure from the urethra, into which is constantly being absorbed urine containing pyogenic bacteria, and the rest is easy. This process is a very slow one, taking weeks, months, or even years before much impression is made. The condition is continually made worse if the stricture or obstruction happens to be, as it usually is, at about the end of the most dependent portion of the urethra and in a straight line from the bladder, so as to receive the direct propulsive force of the muscular efforts to expel the urine. Having thus got out into the layer of cellular tissue, the decomposing fluids and gas work their way in the direction of least resistance under the fascia, through interstices of the superficial fascia at its pubic attachments, to the inguinal region, along the abdominal wall and into the cellular tissues of the scrotum at the same time, the fascia often, as in the case reported above, being dissected from the aponeurosis of the superior oblique in various directions and long spaces, even extending into and beyond the lumbar region. Infection in this case possibly occurred at the passage of the catheter.

The treatment is simple, direct, and imperative. Perineal swelling without external injury means urinary infiltration, always excepting the recto-vesical abscess, which at times extends along this region. The only safe course in such a case is a prompt and generous incision into it and drainage of the urethra and bladder. By such treatment urethral extravasation can always be prevented and, after it has begun, relieved. If the extravasation is not too extensive, or the treatment too long delayed, the prognosis is always good. At the operation the urethra should be cleared of all strictures by an internal urethrotomy.

Applications of hot bichloride-of-mercury gauze 1 : 6,000, or carbolic gauze 1 : 40, to the perineal region and the other affected tissues will be of great assistance to deplete and drain the infiltrated structures.

POISONING BY OIL OF WINTERGREEN.

By B. PILLSBURY, M.D.,
MIDDLETOWN, N. Y.

I REPORT this case since I find, among such records as I have examined, but one case of poisoning by oil of wintergreen, that one ending in recovery. Gilbert G——, a middle-aged farmer, took by mistake for whiskey two ounces of oil of wintergreen at 4 P.M. He went about his work, but in two hours began to have a copious diarrhœa, which continued constantly until his death. His daughter, with rare good judgment, gave him mustard as an emetic, the whites of a dozen raw eggs, milk, and very little water. It was not till near 9 P.M. that a doctor arrived. He found the patient sweating prodigiously, feeling as if on fire inside; pulse 100, not intermittent; the skin was aflame. On the following day the skin was still intensely red, and the victim was harassed by a terrific itching. In the afternoon the pulse was still non-intermittent, but running as fast as possible. The odor of oil of wintergreen was perceptible in the fecal evacuations. Death occurred from exhaustion forty-one hours after the wintergreen was taken.

EXTRAVASATION OF URINE.[1]

By JAMES R. HAYDEN, M.D.,
CHIEF OF CLINIC AND INSTRUCTOR IN GENITO-URINARY AND VENEREAL DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY, NEW YORK; ASSSISTANT VISITING GENITO-URINARY SURGEON, BELLEVUE HOSPITAL.

THE serious nature of urinary extravasation is so apparent that I trust a brief report of the following cases may possibly be of interest, especially to those who are called upon to treat this grave and oftentimes fatal complication of tight urethral stricture.

CASE I.—Scrotal extravasation. The patient, a man sixty-nine years of age, has had gonorrhœa twice, the first attack thirty years ago, the second attack fifteen years ago. He says he has been troubled with more or less difficult, frequent, and painful urination for the past ten years, but has never had complete retention. Twenty hours before admission and without apparent cause he was suddenly seized with intense pain in the perineum, and in a short time the scrotum began to swell and became very tender. He then had a constant and intense desire to urinate, but was able to pass only a few drops, after violent and prolonged straining.

Examination on admission: Patient entered Bellevue Hospital in a state of collapse. Temperature, 102° F.; pulse, 90 and feeble; respiration, 16. The urine is purulent and ammoniacal. The scrotum is three times its normal size, blanched, shining, and œdematous, and very tender on manipulation. There is no swelling in the perineum, penis, or pubic region, although the perineum is sensitive if touched or pressed upon. There is a dense, fibrous, and filiform

[1] Read before the Genito-Urinary Section, New York Academy of Medicine, March 21, 1900.

stricture situated about the middle of the bulbous urethra. The prostate is somewhat enlarged in the rectum, but not tender.

Treatment: The patient was etherized, and an external urethrotomy performed. The stricture having been freely incised, a No. 30 French sound was passed from the meatus. No urine was found in the perineum, the tissues of which looked perfectly normal. The bladder was explored and drained by means of a large perineal tube. Several deep incisions were then made from the top to the bottom of the scrotum, and a large quantity of foul, decomposing urine liberated. The sloughing scrotal tissues were freely irrigated with peroxide of hydrogen and hot saline solution, dressed with moist saline gauze, and supported. The patient's condition now became so precarious that he was given a saline infusion and the usual stimulants hypodermically. He rallied nicely and made an uneventful recovery; and now, one and a half years after the operation, he urinates normally, passing a practically clean urine and taking a full-sized sound with ease. In this case sounds were passed every other day, and the bladder and urethra were irrigated morning and evening.

Case II.—Extravasation into spongy body. The patient, forty-three years of age, has had gonorrhœa several times, the first attack fifteen years ago, the last one two months ago. He has had more or less difficulty in urination for several years, but never complete retention. Ten days after the onset of the last attack of gonorrhœa, he began to have frequent, painful, and difficult urination day and night, which was followed in a few days and without apparent cause by a hard, tender swelling in the perineum, which gradually crept forward along the under surface of the penis.

Examination on admission: Temperature, 102° F.; pulse, 100; respiration, 32. There is a thick, purulent urethral discharge. The urine is ammoniacal, very cloudy from pus, and is passed in drops after much effort. There is a fibrous stricture two inches from the meatus, which admits with difficulty a filiform guide that passes unobstructed from this point to the bladder. The perineum is very tense and bulging, caused by the swelling of the bulb of the corpus spongiosum, which swelling is sharply limited to the spongy body and extends to within two inches of the meatus. The glans is normal. The swelling is very tender, dense, somewhat fluctuating, and yields on aspiration a thin, bloody, ammoniacal, and urinous fluid.

Treatment: The patient being etherized, the stricture was cut with a Fluhrer-Maissoneuve urethrotome, and a full-sized sound was passed from the meatus to the bladder, showing the rest of the canal to be free from stricture. External urethrotomy was then performed for bladder drainage. The corpus spongiosum was freely incised along its entire length, and a surprisingly large amount of thin, bloody, purulent, and ammoniacal urine liberated. The incisions were freely irrigated and dressed as in Case I., the patient having the same local and internal treatment. In eight weeks the patient was discharged from Bellevue Hospital, all wounds having cicatrized, the urethra taking a full-sized sound, and the patient urinating normally. The urine was acid in reaction, and clear, but contained a few light flakes.

The point of interest in this case is, that although the stricture was situated near the meatus, the break in the urethra must have occurred in its bulbous portion, as the extravasation began there and extended slowly forward to the stricture, but did not invade the glans itself, probably on account of the involvement of the corpus spongiosum by the stricture tissue, as the whole thickness of that spongy body was hard and dense at this point.

Case III.—General extravasation. The patient, thirty-seven years of age, eight years ago had a very severe attack of gonorrhœa, from which he says he has never recovered, as ever since that time there has been an increased frequency of urination. Five years ago he had complete retention of urine following alcoholic excess; this was relieved by catheterization. For the past few months he had been urinating every fifteen minutes during the day and hourly during the night, each act being accompanied and followed by tenesmus, during a recent and severe attack of which the patient noticed a bleeding and painful mass protruding from the rectum. Five days ago, after a more violent and prolonged attack of tenesmus than usual, two swellings suddenly appeared, one above the symphysis pubis and another in the perineum. After forty-eight hours these swellings became very hard and painful, and the integument over them was reddish in color. The patient was now in such distress that he entered Bellevue Hospital.

Examination on admission: The patient is poorly nourished, thin, and anæmic. Temperature, 102.4° F.; pulse, 110 and feeble; respiration, 24. The urine is cloudy, alkaline; specific gravity, 1.020; albumin twenty per cent.; no sugar or casts. There are considerable pus, red blood cells, and bladder epithelium. There is a firm, dense, filiform stricture, situated at the bulbo-membranous junction. The anterior abdominal wall, from the symphysis pubis to the umbilicus and between the iliac spines, is dark red in color, œdematous, and tender, and gives a gaseous crepitation on pressure. The scrotum and perineum are in the same condition, except that the skin of the scrotum is shining and blanched. The penis is normal. The rectum is prolapsed, bleeding, and held tightly by the sphincter.

Treatment: The patient was etherized, the sphincter dilated, and the prolapsed gut reduced. An external urethrotomy was then performed, the stricture thoroughly divided, and a full-sized sound passed from the meatus. The bladder was drained by a large perineal tube. The perineum was filled with greenish-black gangrenous and sloughing tissues, from which exuded pus and ammoniacal urine, giving rise to a most horrible odor. As much of these tissues as possible were liberally cut away, and the perineum freely incised on either side of the urethrotomy cut. The same treatment was applied to the scrotum, whose tissues were infiltrated with decomposing urine and in a sloughing condition. Longitudinal sections were then made over the infiltrated abdominal area down to the muscles, and a large quantity of foul gas, pus, and ammoniacal urine liberated. The sloughing tissues and fat in the prevesical space were then removed through the incisions, all of which were thoroughly irrigated, drained, and lightly packed with strips of gauze. The dressings were changed and wounds irrigated every three hours, day and night, for the first few days.

Immediately after the operation, the temperature rose to 104.4° F., the pulse became very feeble, and the patient passed into a condition of extreme shock. He was infused with saline solution, a quantity of which, with a few ounces of brandy, was injected hot into the rectum. He was also stimulated hypodermically. The patient rallied slowly but steadily after the operation, the temperature and pulse gradually becoming normal. The same local and internal treatment was employed as in Case I. On the fiftieth day after operation all of the wounds were healed, and the patient was passing a clear urine naturally.

From a study of the above cases, which have been selected as illustrating the usual forms of urinary extravasation, we are warranted in drawing the following conclusions, in regard to the treatment of this condi-

tion: (1) The location of the stricture or strictures, and their immediate relief by internal urethrotomy, external urethrotomy, or a combination of both; (2) through bladder drainage by means of a large perineal tube, passed through the external urethrotomy wound; (3) free incisions into all areas of extravasation, with liberation of urine, gas, and gangrenous tissues, and their copious irrigation; (4) through drainage and frequent irrigation of these incisions, with change of dressings, which should consist of moist saline gauze and hot saline solution, rather than iodoform, bichloride, or carbolic, on account of the possible toxic effects of the latter, on a subject who is already in a more or less precarious condition; (5) frequent urethral and bladder irrigations, together with the occasional passage of full-sized sounds, and internal medication to keep the urine in a normally acid condition.

ALVEOLAR SARCOMA OF UTERUS.[1]

By A. E. ISAACS, M.D.,

ASSOCIATE PROFESSOR OF SURGERY, NEW YORK SCHOOL OF CLINICAL MEDICINE; VISITING SURGEON, BETH ISRAEL HOSPITAL.

FANNIE K——, twenty-one years old, cigarmaker, not married, was first seen by me at her home on October 9, 1898. She gave no history of previous sickness or abdominal trouble, except that she never menstruated, but had nose-bleed pretty regularly every month. Her present trouble began about a week previously with a severe attack of abdominal cramps, which was only temporarily relieved by an enema and free movement of the bowels. The cramps returned promptly with pain and tenderness all over the abdomen.

Examination showed a temperature of 104.6°; pulse, 120. The whole abdomen was distended, tense, and very tender. There seemed to be some induration in the right iliac fossa, but this could not be definitely ascertained on account of the tenseness of the abdomen. The bowels had not moved in a couple of days. There was no vomiting, but nausea was present. A vaginal examination was not permitted, and the rectal examination was so painful as to prove unsatisfactory. There was a very sparse growth of hair on the genitals. The breasts were normal.

Although no diagnosis could be made, appendicitis was suspected, and the patient was transferred the same evening to the Beth Israel Hospital to be ready for operation should it be found necessary. At the hospital I put her on small repeated doses of calomel, followed by a high enema, which gave a good fecal result, and by the next morning her temperature was down to 100.5°, and pulse to 102. She vomited some dark-colored fluid this day. Her bowels were kept free with salines and enemata, and within a few days her condition was very much improved. After one week's stay in the hospital and until she left, her temperature remained between 99° and 100.5°, and pulse 90 to 104. The tympanites and abdominal tenderness subsided, so that on external palpation a smooth symmetrical central tumor could be felt occupying the site and about the size of a four-and-a-half months' gravid uterus. Of course this suggested either untruth as to previous history, and pregnancy, or uterine retention of the menstrual flow, and in either case a coexistent pelvic inflammation. She positively refused to allow any vaginal examination or any operation, and left the hospital October 25th rather than submit to examination.

Almost three weeks later, on November 13th, she applied for readmission to the hospital, willing now to submit to any treatment found necessary. She had become worse after leaving the hospital, and was bedridden most of the time. Her abdomen was very large and almost filled now with the uterine tumor. Defecation and micturition were both painful. Both legs were œdematous. She was much emaciated and exhausted. Temperature, 101.3°; pulse, 128. Vaginal examination disclosed a normal virgin vagina, an impervious cervix as far as the finger could judge, and a large abdominal tumor occupying the site of the uterus, which was supposed to be that organ distended with retained menstrual blood, complicated with surrounding inflammation secondary to that condition. This examination was made on the table under anæsthesia immediately before the operation, in which Dr. A. Brothers was kind enough to assist me.

The patient being in the Trendelenburg position, an incision was made in the median line between the umbilicus and pubes. The hand introduced into the abdominal cavity felt a large, smooth, soft median tumor filling the whole pelvis and extending upward to a point half-way between the umbilicus and xiphoid. The transverse colon lay across the upper portion of the tumor and was firmly adherent to it. The anterior abdominal wall below a transverse line midway between the umbilicus and pubes was firmly adherent to the growth. Posteriorly also in the pelvis the whole lower portion of the tumor was adherent. To ascertain the contents of the tumor, an aspirator needle was introduced, which gave only a few drops of blood-stained serum. A large cannula gave the same result. Incision into the tumor showed that it was composed of soft grayish tissue interspersed with small serous collections, some clear, some bloody, evidently a malignant growth.

The abdominal incision was enlarged to the upper limit of the tumor and downward to the pubes; the adherent transverse and descending portions of the colon were with difficulty separated from it, and the fundus of the tumor was delivered through the incision. The attempt was made to extirpate the tumor entire, that is, including the uterus, but this proved impossible on account of the very extensive adhesions. The whole length of the uterine sac was incised, and after scooping out about one-third of the tumor piecemeal the rest was enucleated in one mass. The abdominal cavity, then the tumor cavity were flushed out with hot saline solution, and the abdominal incision was closed to somewhat below the umbilicus. The redundant uterine sac was cut away and the circumference of the remainer stitched to the circumference of the remaining peritoneal opening, leaving the peritoneal cavity open at its upper angle, where a strip of gauze was introduced for drainage. The tumor cavity was packed with iodoform gauze.

The patient was in very poor condition after the operation, necessitating all manner of stimulation, but she was brought around and within a few days was comparatively much improved, though she had to be constantly stimulated. Œdema of the legs disappeared, and pain with stool and urination subsided.

The tumor promptly began to grow again, and in spite of repeated removals of new growth gradually filled up the pelvic sac again, and about three weeks after the operation it began to protrude through the wound. During the fourth week the woman began to decline again, and died of exhaustion on December 20th, five weeks after operation.

Pathological examination of the tumor by Dr. H. T. Brooks: "Complex neoplasm of embryonal origin frequently designated as 'blastoma.' It is very closely related (this one) to alveolar sarcoma, though there are also some areas much like adeno-carcinoma."

The points of special interest in the case are: (1) Whether uterine retention of menstrual flow was the cause of the subsequent malignant growth. (2) The

[1] Specimen presented at a meeting of the Eastern Medical Society, December, 1898.

rapidity of the growth of the tumor, which in three weeks from the time she left the hospital till she returned grew from the size of a four to four-and-one-half months' pregnant uterus to that of a full-term uterus. (3) The repeated attacks of surrounding peritonitis simulating other intra-abdominal inflammations, and likely to be mistaken for them.

A CASE OF ENORMOUS ELEPHANTIASIS.

By PHILIP F. ROGERS, M.D.,
ASSISTANT IN ANATOMY, MILWAUKEE MEDICAL COLLEGE.

THE patient, a Russian Jewess of the lower class, found her way into the clinic at the Milwaukee Medical College, and was exhibited there before a large audience by Professor Earles.

She was born near Kieff, in southwestern Russia, twenty-six years ago, and lived there until coming to Milwaukee some sixteen months since. The family history is negative. Parents, two brothers, and two sisters—one of the latter older than herself, all the rest younger—are living and well. She herself had nothing more serious than the ordinary sicknesses of childhood up to twelve years of age, and was a lively, romping girl.

At the age of twelve she attended a wedding and danced all night, and during the next few days, when cold and wet weather prevailed, was running about barelegged. As a result she was sick abed for some days with fever and headache.

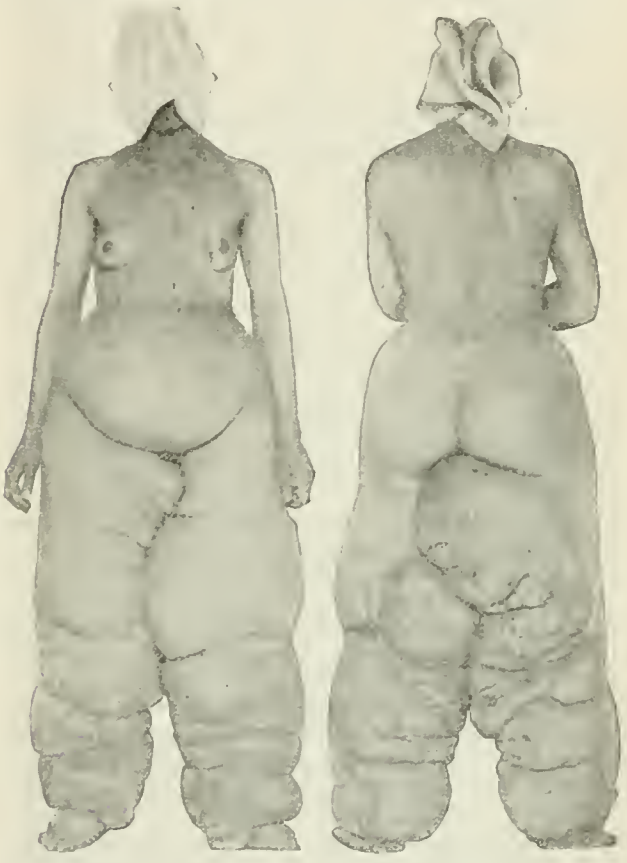
A subcutanous abscess—attributed to the strain of dancing and the subsequent exposure—formed on the inner side of the right knee, was evacuated, and discharged for some time, but finally healed, leaving a small scar, which can still be seen. For six months after this she was as well as ever; then there was noticed a beginning thickening of the skin of the right foot, and it has increased slowly but steadily up to the present time, involving progressively the foot, leg, and thigh. The enormous mass on the upper right thigh she thinks has developed within the past year. Local physicians treated her with medicines and bandaging, in hopes of checking the process, but without success. Specialists in Kieff were consulted. One advised a "let-alone" policy, saying nothing could be done, and that she could live to old age with the disease; another advised a course of hospital treatment; while a third wanted to amputate—the process having at that time not gone above the knee. As the family wealth was at low ebb the let-alone plan was adopted. Three years ago the girl was married!—she explained to me in bad German that "Er hat gewusst, dass das rechte Bein ein bischen dick war," and eight days later she noticed thickening of the left foot and leg. Her husband packed his bundle and stole away to America soon afterward. The process must have been much more rapid in the left than in the right leg, as it has already overtaken and even a trifle outstripped it in measurements.

Sixteen months ago the patient emigrated with her family, coming directly to Milwaukee, and by some hook or crook—her jargon gets too deep for me at times—managed to recapture her recreant husband, and he now lives with her, and follows the profession of rag-picker.

Her present status, aside from the elephantine condition of her legs, is one of good health. Lungs, heart, digestion, and sexual functions are normal; she suffers no pain, and although greatly inconvenienced by her deformity and easily fatigued upon exertion, she does not seem to realize her misfortune so keenly as would one of a higher order of intelligence; she even laughs and jokes about herself.

She performs the duties of her cellar home, and ekes out a pittance by running a sewing-machine, doing piece-work for some sweat-shop. Her gait is waddling and slow, but she mounts street-cars and climbs stairs with tolerable ease. On the street, one's attention would be attracted to her first by her gait, and then by her great breadth across the thighs. Her figure reminds one of the old days when hoop-skirts were in fashion.

As to the clinical appearance of the disease, a detailed description is unnecessary, as the illustrations speak for themselves. I had hung up a white sheet for a background, but finding it a poor contrast to the figure in the prints, it occurred to me to soak the films again, outline the figure with a sharp knife, and scrape the rest of the emulsion off. This left the negative outside the figure very thin and transparent, giving a perfectly dark background so that the body stands out like a statue. One of the side views is unfortunately



somewhat blurred, owing to a slight movement during exposure.

Her measurements are as follows: Height, 5 feet; weight, 248 pounds; chest girth, 32 inches; waist girth, 28½ inches; right thigh, 38 inches; left thigh, 39 inches; right calf, 31 inches; left calf, 29 inches; ankles, 29 inches.

The color of the masses low down is dark red, gradually shading off above to normal flesh tints. The consistency is of board-like hardness below, but above the knees the skin is doughy and œdematous. Some of the fissures are deep enough to conceal the better part of one's hand, and as might be expected the moisture and attrition tend to the production of eczema, although the really excellent care and cleanliness exercised by the patient keep it at a minimum. Tactile, pain, and heat sense are everywhere perfect.

The toes and borders of the feet are normal, and there is quite free ankle motion. She wears low-cut, soft leather shoes, and the stockings might be mistaken for coffee-sacks. No nether undergarments are worn.

Knee action allows flexure at a right angle, and the skin over the patellæ is not very much thickened.

Hip action is perfect. She can stoop and touch her toes with ease—in fact, always stands while pulling on her stockings. The genitalia are only slightly involved. The labia majora are somewhat larger than normal, and their posterior juncture and the perineum are warty. Urination and defecation are easily accomplished. Coitus, she says involves "viel trouble! viel trouble!" The buttocks are perfectly normal, the growth stopping short at the subgluteal fold, but the lower abdominal wall is quite œdematous, and on the right side over Poupart's ligament several tortuous dilated lymph-vessels appear like welts on the skin. Repeated blood examinations have shown no filariæ and no noticeable blood changes.

1130 State Street.

COMPLETE RECOVERY FOLLOWING A SEVERE COMPOUND FRACTURE OF THE SKULL.

By G. REESE SATTERLEE, A.M., M.D.,
NEW YORK.

This case is reported by the permission of Dr. C. T. Parker, the attending surgeon of the J. Hood Wright Memorial Hospital, who was absent at the time and asked me as house surgeon to treat it.

The patient was brought into the hospital by ambulance about 8 P.M., November 4, 1899, having been struck on the head by a stone from a blast. He was a driver, and was found some distance from his wagon. When I saw him, he was conscious, but slightly irrational. Examination showed a large lacerated scalp wound over the right parietal region. Underneath this, close to the interparietal and about two inches back from the coronal suture, was a depressed fracture the size of a fifty-cent piece. A number of small fragments of bone were seen at the bottom of this embedded in the brain tissue in places where the dura had been torn. A large amount of hair and dirt was ground into the cortex with the bone fragments. This corresponded to about the upper part of the motor area of the brain. There was free arterial hemorrhage from the left ear. There were no paralyses nor any symptoms of cerebral compression.

As the patient suffered from considerable shock, he was treated for that, and his wound was cleansed and dressed temporarily. Three hours after entrance, having recovered from shock, he was taken to the operating-room, and under ether the wound was thoroughly cleansed, and the depressed bone was elevated and removed. The hair and dirt were carefully picked out under a continuous stream of decinormal salt solution. On removing the fragments of bone and dirt, the dura was found to be torn badly, and one fragment when dislodged opened up a large ragged tear in the superior longitudinal sinus. This lodgment of bone explained why there had not been a severe hemorrhage previously, and it undoubtedly saved the man's life.

On removing the piece of bone, there was a profuse venous hemorrhage, which amounted to over a quart before it could be controlled. About one inch of the sinus had been torn away and macerated so that it was at first impossible to find the ends. Finally, however, the proximal end of the sinus was packed and the hemorrhage checked. No more fragments of bone being found, a dry gauze dressing was applied. The patient was put to bed, stimulated freely, and given morphine.

The next day at 9 A.M. the left arm and leg became paralyzed. The dressings, being saturated with a bloody discharge, were changed. Retention of urine occurred at 7 P.M. Thinking that the paralysis might be caused by a blood clot on the cortex, I removed the packing and about a pint of very dark blood flowed out, necessitating repacking; no blood clot over the cortex could be found.

On November 6th the left leg was stiff and the reflexes on that side were exaggerated; urination became voluntary. The dressings were soaked with serous fluid.

On November 8th there was a free serous discharge from the wound and from the left ear, accompanied with much thirst and epistaxis. The patient was then placed in a sitting posture to prevent the loss of cerebro-spinal fluid.

On November 12th the packing in the longitudinal sinus was slightly loosened and a wet aluminum acetate dressing was applied to soften the adhesion. On the next day the gauze packing was removed, leaving a sinus about an inch and a half long, at the bottom of which arterial pulsation was very distinct A small strip of gauze was inserted. There had been absolutely no signs of infection or of suppuration. There had been but slight elevation of temperature, and no delirium since the first night.

On November 19th there was a slight protrusion of the brain substance above the outer table of the skull. The top of the head was shaved and a skin flap was drawn over the protrusion and strapped down by adhesive plaster. On the 25th the sinus was nearly healed, the protrusion was reduced by means of the shaving and strapping every day, and the wound was granulating nicely.

On the 28th the paralysis in the extremities was unimproved.

On December 5th the patient was sitting up in bed and had a slight amount of motion in the left lower extremity.

On the 9th he had a limited amount of motion in the left upper extremity.

On the 19th he walked around the bed with assistance. From then on he improved rapidly, and on January 6, 1900, about two months after the injury, he walked without difficulty and was discharged from the hospital cured.

Since that time I have seen him frequently, and he is perfectly well in every respect. He is working hard as a driver, has no weakness in any of the extremities, but has a slight tingling sensation in the tips of the fingers of the left hand. The wound is healed and there is a good firm cicatrix. He has neither headache nor vertigo. His eyesight is excellent. There is some deafness in the left ear.

136 Madison Avenue.

A PECULIAR DELUSION.

By W. MOSER, M.D.,
BROOKLYN, N. Y.,
PATHOLOGIST TO ST. CATHERINE'S AND ST. MARY'S HOSPITALS, AND ASSISTANT ATTENDING PHYSICIAN TO THE GERMAN HOSPITALS.

Many of us have delusions, but we do not necessarily require the services of the neurologist. Medico-legally, neurologists themselves sometimes differ as to the significance of a given delusion. Certain delusions or false beliefs are characteristic of a certain disease or form of insanity; as, for instance, the "delusions of grandeur" in general paresis. Here the unfortunate is laboring under the false belief or delusion that he owns the earth, or, as I recall a case seen more than ten years ago, the individual had the delusion that he was the "king of Ireland." In the same way the "delusions of persecution" suggest paranoia.

Certain delusions pertaining to the individual's health are sometimes called "hypochondriacal delusions" and sometimes classed as "neurasthenic," or the delusion may be more pronounced and suggest melan-

cholia. The form of delusion to which I wish to call attention is one in which the patient does not believe himself to be afflicted with some particular malady, but labors under the peculiar delusion that there are reptiles in the abdomen. This patient has been under observation for more than two years, and comes regularly to St. Catherine's Dispensary to have me either destroy or expel the snakes, lizards, and blindworms which inhabit her abdomen. The peculiarity of this delusion is that her menagerie is made up of reptiles and excludes all other animals. There is not merely a delusion or false belief of the presence of reptiles in her abdomen, but the patient distinctly feels their heads and insists that they are alive. Whether this is a case of melancholia or a distinct psychological phenomenon, I am unable to say. I fear she will retain this menagerie in her abdomen until her mind is forever set at rest.

These psychological phenomena or delusions are not infallible signs in diagnosis, but sometimes are a great aid in prognosis.

Therapeutic Hints.

Tuberculosis.—Drugs containing iodine are the best aids to immunity. They are best given by inunction. The essential oils, and especially peppermint and thyme, unfit the tissues as soil for the propagation of bacilli.—F. L. Flich.

℞ Oil of thyme,
Oil of eucalyptus,
Oil of cinnamon.....āā ♏ lxxx.
Oil of olives (steril.)..... ʒ iiiss.
Iodoform..... ʒ i. gr. xv.
Bromoform..... ♏ xxx.
M. S. Empty 45 minims by means of a long curved syringe into the trachea.

—Mendel.

Pernicious Anæmia.—

℞ Fowler's solution..... ʒ iiss.
Acid phosphate..... ʒ iij.
Bone-marrow extract.....ad ʒ viij.
M. S. Dessertspoonful after each meal

J. N. Danforth.

Laxative Electuary for Children.—

℞ Tears of manna..... 25 gm.
Calcined magnesia,
Washed flowers of sulphur.....āā 50 "
White honey..... 20 "

In habitual constipation one or two soupspoonfuls in a cup of hot milk. For a purgative effect three or four spoonfuls.—Ferrand.

Enterocolitis (Muco-Membranous) in the Adult.—Castor oil is the best laxative. As a succedaneum:

℞ Magnes. calcin.,
Sulphur. loti,
Potass. bitart.....āā 20
S. A teaspoonful before each meal.

—G. Sée.

℞ Podophyllin,
Euonymin.....āā 0.40
Ex. bellad..... 0.20
Ext. hydrastis canad..... 1.
M. ft. pil. No. xx. S. One or two at dinner.

—G. Lyon.

Picric-acid enemata, 1 in 120.—Chéron.

Large enemata of oil.—Fleiner.

In the attacks of paroxysmal pain repose in bed, hot compresses, belladonna by the mouth, or morphine under the skin.

Nervous Insomnia.—Render a tumblerful of sour curds and whey alkaline with bicarbonate of sodium; sweeten and grate nutmeg on the top. Give hot.

Stomach Lavage.—

℞ Sodii biborat..... ʒ ij.
Creolini..... gr. iv.
Acidi salicylici..... gr. xviij.
Thymolis..... gr. iv.
Use in washing once a day after a clear-water lavage by means of a siphon tube.

—Rosenheim.

Otalgia.—

℞ Quin. sulph..... gr. xviij.
Potass. iodid..... gr. xxxvi.
Sacch. alb..... gr. xlv.
M. ft. chart No. vi. S. One twice a day.

When acute give antypyrin in initial dose of gr. xvi. with half this quantity every hour subsequently. In chronic forms:

℞ Zinci oxidi,
Rad. valerian.,
Ext. hyoscyami. alc.....āā ʒ ss.
Pulv. et ext. glycyrrhiz..... q.s.
M. ft. pil. No. c. S. One a day, and increase from one a day up to thirty, then decrease.

—Politzer.

Whooping-Cough.—Pure turpentine and sweet oil should be applied to the chest night and morning until distinct redness is produced.—*Journal des Praticiens.*

Rachitis.—

℞ Phosphorus..... 0.01 cgm.
Ol. morrhuæ..... 1,000. gm
Saccharin..... 0.10 cgm.

—Kassowitch.

Painful Periods.—Menstrual pains are said to be relieved by

℞ Codein..... gr. ss.
Chloral.,
Ammon. brom.....āā gr. viij.
Aquæ camph..... ʒ i.
For one dose. Repeat.

Foul Breath.—Retained secretion behind the plica tonsillaris is a frequent cause. Exclude a dental, nasal, œsophageal, or respiratory-passage origin. Give antiseptic gargles.—Fraenkel.

Repair of Old Lacerations.—The Emmet operation and all denudation methods of the vaginal orifice, which are the operations in almost universal use today, fail to restore in any degree the real pelvic floor. They are suitable in lacerations of the so-called perineal body, but not when the muscles are torn. The method which I wish to present involves a resection of a portion of the pubo-rectalis muscle so as to shorten up the pelvic floor. It is performed as follows: When laceration of the perineum is present, the denudation of this part is made in the usual manner. If this body be intact the denudation is omitted. An incision is then carried up each lateral wall of the vagina from 3 to 5 cm., a little posterior to the centre. The vaginal wall is raised in a flap each way from the incision. The edge of the muscle can now usually be felt, and an incision parallel therewith is made through the perivaginal connective tissue, exposing the muscle, which may easily be dissected out with the handle of a scalpel, blunt dissector, or the finger, ventrally as far as the symphysis and dorsally until it curves around posterior to the rectum.—M. L. Harris, in *The Canadian Practitioner and Review*, April.

Appendicitis.—There is a general agreement as to high mortality in severe acute cases under any treatment, the successful issue of mild cases regardless of treatment, the freedom from danger of the interval operation in chronic cases, and the large percentage of relapses after one attack. While purgatives may cut short a mild attack they may cause perforation in crit-

ical stages. Opium is safe but not curative. Literature abounds with ridiculously contradictory assertions which a statistical study should obviate.—H. H. YOUNG, *Maryland Medical Journal*, April.

Dysmenorrhœa.—The spasmodic element can be eliminated by belladonna. If pain continues after a few doses it is because mechanical or congestive elements are present, since the neuralgic element is to a great extent eliminated by the drug. A suppository containing one or two grains of the extract is the best way to administer, repeated every two to four hours.—WILLIAM MURRAY.

New Instruments.

A POCKET AND CANTEEN FILTER.

BY ROSWELL O. STEBBINS, D.D.S.,
NEW YORK.

THIS filter is constructed of aluminum. First, a very finely perforated metal disk acts as a strainer; second, a disk of specially prepared filtering-paper will eliminate all decayed vegetation and other solids held in suspension or solution in the water. To the pocket filter is attached a tube of pure rubber, through which water may be sucked slowly, yet freely enough to quench thirst readily.

The canteen filter is attached to the end of an aluminum tube, which is passed through a cork as

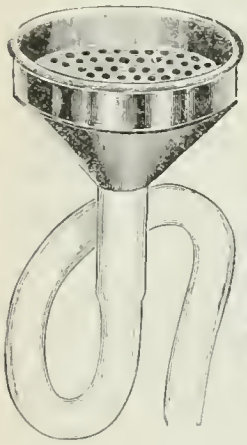


FIG. 1.

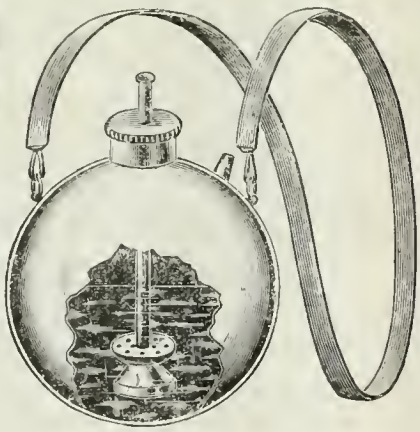

FIG. 2.

shown in Fig. 2. A disk with holes of moderate size is placed above the filter to prevent any large substance from passing into the canteen while it is being filled with water.

AN INSTRUMENT FOR DETERMINING THE OBSTETRIC CONJUGATE.

BY ROBERT R. ROME, M.D.,
MINNEAPOLIS, MINN.,
PROFESSOR OF OPERATIVE OBSTETRICS, MEDICAL DEPARTMENT, UNIVERSITY OF MINNESOTA.

THE subject of pelvimetry is of importance to every physician who may be called upon to officiate at the birth of a human being. We may perhaps truthfully say that abnormal conditions are on the increase, but we are being provided with artificial aids to overcome these abnormal conditions. There was a time when the finger and its nail was the sharpest and only curette at our disposal. But the ingenuity of man has made a finger of steel mounted with a nail of metal which can be introduced and manipulated where the finger of man is forbidden to enter. There was a time when the hand of the obstetrician was the only aid at his command with which to effect a delivery. Now we have forceps of all forms made to fit the presenting part of the child, making artificial delivery safer and easier to all concerned.

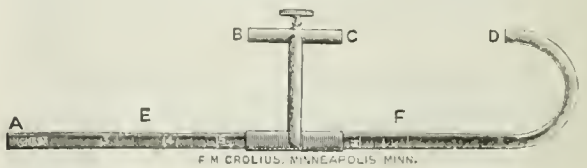
Baudelocque made use of his fingers to estimate the obstetric conjugate; he gave us an instrument with which to estimate the diameters of the pelvis externally; much suffering and many lives have been saved by the faithful use of that instrument. We can determine by external pelvimetry whether we are dealing with a justo-major, a justo-minor, a simple flat, a rachitic flat, a Roberts, a Naegele, or a normal pelvis. But Baudelocque's fingers, employed to measure the distance from the promontory to the subpubic ligament or the diagonal conjugate, from that measurement a guess being made of the true or obstetric conjugate, must be replaced by an instrument of precision.

The instrument about to be described I believe will fill a long-felt want. It has the three elements combined which will recommend it to every practising physicians, namely, simplicity, accuracy, and practicability.

External pelvimetry leaves us to guess at the thickness of the bony structures, *i.e.*, the last lumbar vertebra and the symphysis pubis. When the fingers are employed as taught by Baudelocque all that can be determined with any degree of accuracy is the diagonal conjugate, and from this we are to subtract two-thirds of an inch, providing the following "ifs" are present: if the diameter is the longest side of the scalene triangle, if the symphysis is of normal thickness, if the symphysis is of normal height, if the symphysis forms the normal angle with the pelvis, if the sacrovertebral articulation or joint is of normal thickness. Should any one of these "ifs" deviate from the normal standard we have introduced an error into the problem, and the answer will be incorrect.

The instrument I have devised is twelve inches in length, and the semicircle described by the hook is two and one-half inches in diameter. The shaft is hollow and oval, while the hook is round. The shaft is provided with an inch scale on one side and a centimetre scale on the other. The sliding T-bar is provided with a set-screw with which it can be made firm when necessary.

How to use the instrument: First find the height of the symphysis, *i.e.*, from subpubic to suprapubic ligament or tissues; at about the upper third of the total height make a mark; this corresponds to the thickest portion of the pubic bone. Bring the patient well over the edge of the table, flex the knees and thighs, and support them. Lubricate the fingers of one hand, introduce them into the vagina, retract the perineum by continuous and firm pressure, lower the arm and elbow so as to give an upward direction to the fingers in the vagina. Now request the patient to raise the hips, and follow the hollow of the sacrum until the middle finger is firmly fixed on the true sacral promontory. Slide the shaft along the palmar surface



of the fingers until the end *A* is made to take the place of the end of the middle finger, the latter being moved a little to one side. The shaft being held in position by the index and middle fingers, slide the T-bar toward

the symphysis until the end *B* is made to press firmly on the mark previously made. Turn the set-screw and remove the instrument. Note carefully the number of inches or centimetres from the end *A* to the end collar nearest the end *A*.

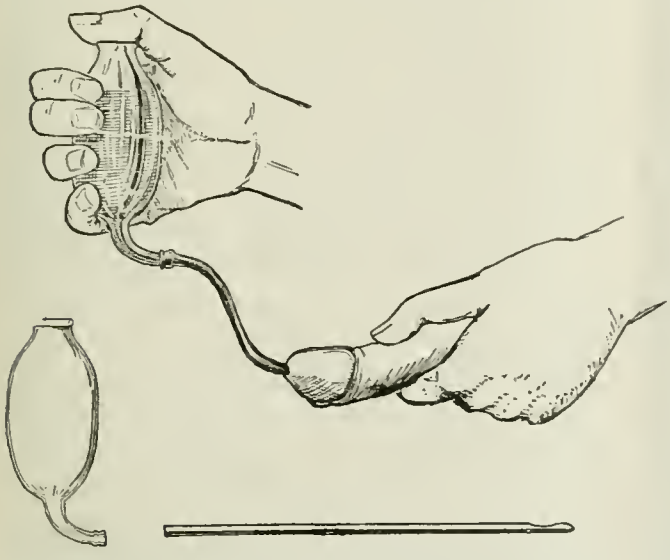
Reverse the instrument; pass the hook into the vagina with the end *D* upward and back of the pubic bone. Steady the instrument in this position while the T-bar is moved toward the symphysis until the end *C* is made to press firmly on the mark as before. Now turn the set-screw. Read off the thickness of the symphysis on the scale provided for that purpose. Loosen the screw; slide back the T-bar before removing the instrument in order to avoid bruising the soft parts about the pubic bone. Subtract the last measurement or thickness of the symphysis from the first measurement, and the difference will be the true or obstetric conjugate.

A GLASS HYDROSTATIC-PRESSURE IRRIGATOR FOR THE URETHRA OR BLADDER.

By ROBERT COLEMAN KEMP, M.D.,

NEW YORK.

In the injection of solutions into the urethra with the hand syringe for gonorrhœa, etc., especially if the treatment is carried out by the patient, there is always the danger that, through too forcible or irregular pressure, the fluid may pass too far up the canal and carry infected material to the healthy parts. Unfortunately this accident is by no means extremely rare, and as a result we may have posterior urethritis, and with it associated epididymitis, seminal vesiculitis, etc., or even a gonorrhœal cystitis. The question of the proper instrument for irrigation is always important, and there are catheters with a back flow (the current directed toward the meatus), double-current instruments, and such devices. Some advocate gentle irrigation with the fountain syringe hung very low, so as to secure but light pressure. There is always a tendency to elevate such a reservoir, it seems to me, higher than it should be, and the force seems too strong. In the accompanying illustration I present a cheap and simple glass irrigator for the urethra, which can



also be employed to wash the bladder by gentle siphonage. It consists of a glass bulb—preferably annealed to secure strength—the capacity of which is ℥ iiss.–℥ iii. The bulb is drawn out into a curved outflow tube at the bottom, to which a small soft-rubber catheter is to be attached.

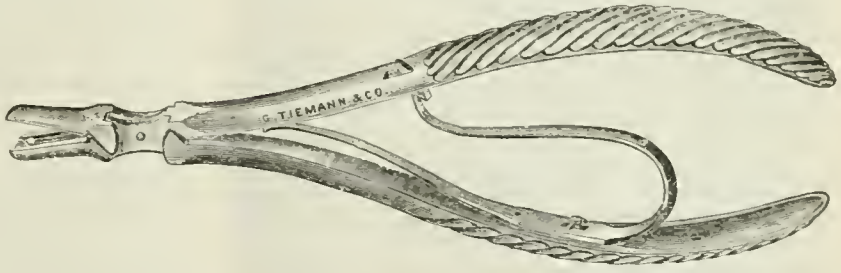
An opening of small size may be cut in the catheter about half an inch from the eye on the opposite side, the edges of this heated over a flame, and quickly wiped with the wet finger, to transform it into a velvet eye. Thus we secure an outflow on both sides of the instrument. The catheter may be cut by the physician the length he desires the irrigation to pass into the organ, allowing sufficient length in addition for proper elevation of the bulb. There seems to be just sufficient pressure to wash around the tip of the catheter and flow back and out of the meatus. The position employed is well shown in the illustration. If it is desired to wash the bladder, the return flow is secured by lowering the bulb below the bladder level, and if necessary starting the flow by siphonage—with a little water remaining in the bulb—just as in lavage. A simple hydrostatic irrigator may be improvised as follows: Take a cheap glass syringe (sharp pointed) and unscrew the end cap, removing this and with it the piston and plunger. Attach the catheter to the point of the syringe. Fill this with solution and control the flow with the thumb as before.

A NEW NEEDLE HOLDER THAT WILL NOT BREAK NEEDLES.

By W. H. LUCKETT, M.D.,

NEW YORK.

The accompanying one-half-size cut is an excellent illustration of a new needle holder or forceps, the chief claim of which to originality lies in the construc-



tion of the jaw. The average needle holder has, when grasping an ordinary surgical curved needle, three points of contact with the needle: two points of contact, the power and the resistance, are on the concave, and the third point of contact, the fulcrum, is on the convex surface between the power and resistance, thus making a lever of the first class, so that the needle frequently breaks, when tightly grasped, or else, if loosely held, it turns in the holder.

I have labored, therefore, to construct a holder that will not make a lever of the needle, and have accomplished this by raising a flange of softer metal around the edges of the surfaces of the jaw, so that it will grasp the needle at four points of contact: two on either side of the needle and almost directly opposite each other.

The direction of the force exerted by the holder being through the needle from opposing points, renders it impossible to break the needle. Considerable trouble was encountered by the makers, G. Tiemann & Co., in finding metal of the proper malleability for the flange. The detachable spring catch has been placed sufficiently far forward that it can be manipulated by the thumb.

Medical Items.

Enteric Fever among Soldiers.—A writer in the London *Lancet*, commenting on the British Army Report for 1898, and speaking of enteric fever among soldiers, says: "A glance at the daily journals is unfortunately sufficient to show the important rôle which disease and notably enteric fever occupies in the history of the South African war. This fever is a veritable scourge of armies in the field, and this has been even more the case with the expeditionary armies of other military powers than ourselves. We find abundant evidence of the prevalence of enteric fever in the report under review—at Ladysmith, Pietermaritzburg, Wynberg, King William's Town, and Simonstown, for example, long before the arrival of the British expeditionary force had taken place in that country, and we are therefore not required to have recourse to the theory of any fresh introduction of the disease there by the newly arrived troops. As the subject is one of vast importance in relation to the diseases incidental to war service and camps, we need make no apologies for dealing with it, more especially, as we said on previous occasions, it is a generally recognized fact, be the explanation what it may, that there is an increased liability to contract typhoid fever at certain periods of life; in other words, that there exists an enteric-fever age period which includes the time during which soldiers are serving with the colors in all short-service armies. But a still more powerful predisposing cause is recent arrival in a tropical or subtropical climate, especially during the hot season. As far as India is concerned this susceptibility or vulnerability of the European constitution to enteric fever in fresh arrivals is at its maximum during the first year, markedly declines the second and third year, and is, practically speaking, nearly exhausted between the third and fourth year of Indian service. It is not, of course, pretended that these are the only disease factors, for if the real cause of enteric fever be the bacillus of Eberth and Gaffky, then it follows that the presence of the specific germ or micro-organism is indispensably necessary to its production, but this bacillus must in that case be much more widely distributed in nature than our present knowledge would lead us to suppose, in order to account for all the enteric fever that occurs; or, to put it in another way, the number and extent of the infected areas on the surface of the globe must be greater than has hitherto been thought to be the case."

Railway Hygiene in the United States.—An investigation made in Massachusetts with reference to certain infectious diseases in 1891 showed that smallpox, diphtheria, scarlet fever, and measles were relatively more prevalent in the towns situated on railway lines than they were in those towns not so connected. Out of 2,298 deaths from smallpox which occurred in twenty years in that State, only thirteen occurred in towns not directly on some line of railway communication. The same fact was noted, though in a less marked degree, in regard to diphtheria, scarlet fever, and measles. Undoubtedly there are many cases of persons having unrecognized infectious disease travelling on railways; hence, measures are necessary to provide, first, for the thorough cleansing and disinfection of cars and their furnishings, especially of sleeping-cars, at the ends of their respective routes or lines of travel; second, for a careful supervision of the water-closets on the trains, and that they are not allowed to be used at or near the stations in cities and towns. It is quite practicable also, and desirable, to require that some disinfectant of recognized potency be added to the water used for flushing purposes when such is provided; third, the water supply, the food supply, and the ice-supply used on long lines for dining-cars and lunch rooms at stations should receive careful supervision. It is also desirable that the milk used on dining-cars and at stations should be procured of stated parties, and that they should be held responsible for its quality and for the cleanliness of the dairies from which it is obtained; fourth, measures are necessary for the exclusion of persons sick with infectious diseases, from public conveyances (cars and steamers), and if this is impracticable to provide for their isolation in separate cars or compartments.—"Public and State Hygiene in the United States," by SAMUEL W. ABBOTT.

Marriage of First Cousins.—Mr. Jonathan Hutchinson says: "There is nothing likely to be prejudicial to offspring in a consanguineous marriage *per se*, but if there be in the family any definite tendency to such diseases as tuberculosis, cancer, or insanity, there is a risk that it may be intensified. On the other hand, if the family has a good life history, then there may be greater security in such a marriage than in one with a stranger whose antecedents may probably be less well known.

Deaths from Sunstroke at Aldershot, says the *British Medical Journal*, aroused a great deal of interest among members on both sides of the House of Commons. It would seem that some 18,000 men were paraded for the field day on June 11th, and that in consequence of the excessive heat no fewer than 28 men were received into the hospital, of whom 4 died while 29 others were injuriously affected. The troops covered in their march some fourteen miles, and wore the ordinary field cap. This afforded insufficient protection, and the commander-in-chief has ordered that helmets should be worn in hot weather and that troops unprovided with helmets are not to take part in exhausting operations. There were also regrettable defects in the provision of food and water for the men. The whole incident exhibits, members think, a lapse from common sense and ordinary prevision, which strong measures should be taken to prevent in the future.

Malaria in Canada.—Professor Adami, of McGill University, Montreal, supplies an interesting report to the *British Medical Journal* of the tropical and subtropical diseases of Canada. Referring to malaria he says: "With regard to malaria, just as in Great Britain, even to the middle of this century, cases occurred with considerable frequency, more especially in the Fen districts and in Lincolnshire, so here in Canada during times within the memory of old inhabitants I am informed that malaria was not infrequent along the St. Lawrence, even in the neighborhood of Montreal. Now, however, it is only in the most southerly portion of Canada, namely, in the peninsula of Ontario between the great lakes, that malaria is met with, and there not to any great extent. So far as I can learn, members of the genus Anopheles are still present. Some other conditions, however, than the presence of the hosts of the malarial micro-organism would seem necessary for the persistence and propagation of the malarial germ; and when the extraordinary abundance of lakes and large bodies of water throughout Canada is called to mind and the relatively small proportion of the country that has undergone full drainage and full cultivation, the gradual disappearance of the disease becomes a problem difficult to solve. For myself, during the seven years I have been pathologist to the two largest hospitals in Montreal in succession, I have come across but one case of malaria in one who had not been out of the country; this was in an old Red Indian who came from Ontario. Taking into account the enormous

numbers of mosquitos present throughout Canada during the early summer months, and the fact that the further north one goes into Labrador or into Alaska the greater becomes their number, until in some regions during the months of June and July it is almost impossible to live on account of them, Canada should supply a very good ground for the study of the relationship of mosquitos to the conveyance of more than one form of disease."

An Old Argument for Alcohol.—The London *Spectator*, referring to the recent temperance congress, says: "Humanity owes everything worth having to the races which use alcohol. The drinking races have not only conquered but moralized the world. The Jew drank and gave us monotheism and Christianity, the Greek drank and gave us literature and art. The Roman drank and gave us law, the Teuton drank (hard) and gave us the passion of freedom. What have the two great races which rejected alcohol—the Hindoo and the Arab—done to counterweigh the benefits conferred by their drinking rivals?"

The Hospital Scandal in South Africa.—*The Hospital* says: "It is impossible to read without distress, and indeed without the strongest sense of indignation, the revelations made in *The Times* of the 27th inst. by Mr. Burdett-Coutts in regard to the hardships to which our sick soldiers in South Africa have been exposed—exposed, we fear, recklessly and almost wilfully in consequence of the want of foresight displayed by the central administrative authorities, who ought to have known what all experience has taught, that sickness would certainly throw a far more serious strain than wounds upon the medical organization. No doubt we have now in South Africa a far larger force than was contemplated when the war began; but those who sent the men out ought surely to have had the foresight to send out the necessary equipment in addition, and it ought not to have been possible for such horrors to have come into existence as those which Mr. Burdett-Coutts details so graphically as having been seen with his own eyes. No one can doubt that the men on the spot were struggling manfully to meet the terrible strain of supplying the wants of the twenty thousand sick who now occupy the whole track of the army. More than half of these sick, we are told, are down with typhoid fever, and those who know best what care, what cleanliness, what constant attention are required to prevent infection spreading far and wide, will recognize not only the terrible hardships to which our unfortunate soldiers are being exposed, but the serious danger which hangs over the whole expedition from the unchecked extension of this disease. We will not now enter into the details of the horrible neglect which Mr. Burdett-Coutts lays bare, but we will join with him in saying that the whole series of events ought to have been foreseen and provided for. That fever has always been the scourge of South Africa, that Bloemfontein is always a typhoid town, and that this town would of necessity become a point on which our troops would concentrate in large numbers was always known."

The Famine in India.—The London *Spectator* says: "We are happy to record that the famine in India approaches its termination. The monsoon though late has brought copious rains throughout India, and in a few weeks cultivation will be possible. The money-lenders, secure of a future crop, will recommence making advances by which seed at all events may be secured, while the State, we hope, will render assistance in the collection of cattle. The extinction of beasts is a terrible addition to the weight of the calamity. There are still, we believe, men who say that a famine of this kind is all the fault of the system of taxation in India, which, as we quite admit, though not too heavy is wanting in elasticity; but as a matter of fact, the heaviest blow has fallen upon districts still taxed only by their native rulers—Guzerat, Rajpootana, and Kattiawar. There is grave reason to fear that in the wide regions under the first and second names the loss of population from the famine and its sequelæ—cholera, fever, and typhoidal disease—will not be less than one-fifth of the whole, while the destruction of beasts will be in yet greater proportion.

A Plea for Antitoxin.—It is a stock argument with the antivivisectionists against the value of diphtheria antitoxin that the use of this remedial agent has neither lessened the number of cases nor diminished the death rate from diphtheria. It is perfectly obvious, however, that more successful treatment of an infective disease does not necessarily mean a diminished incidence of that disease. No one, it is to be presumed, not even the most pronounced antivivisectionist, would deny that the plague in India is more successfully treated—*i.e.*, that the percentage of recoveries is greater—during the present epidemic than it was in the Middle Ages; but it is to be doubted if the incidence of the disease in many districts is less than it was in former times. The antivivisectionists always quote the death rate, and not, as should be done, the case mortality; if the latter be taken, statistics practically without exception show the great reduction in mortality brought about by the use of diphtheria antitoxin. But this very reduction in mortality brings with it a danger to the community. If the individual who is suffering from diphtheria dies, he is done with, and there is little risk of the spread of the disease from the cadaver. But if he recovers diphtheria bacilli will be present in the throat for a shorter or longer period, even for many months, and while they are present there is always the risk of those with whom he comes in contact contracting the disease. Paradoxical though it may seem, therefore, the greater the number of recoveries, theoretically the greater the number of cases, and so it will be unless isolation be vigorously carried out until all risk of infection is past. A high mortality is really a natural "stamping out" system and would tend to diminish the incidence of the disease.—Dr. Hewlett, in *Treatment*, April.

The Results of the Open-Air Treatment of Phthisis in the Berlin Homes.—Elkan gives the results of the treatment of consumptives in the Malchow Sanatorium for men and that of Blankenfelde for women; 5,581 patients stayed longer than fourteen days, the average time being forty-nine days. The average increase in weight was 4.8 kgm. He divides the patients into classes: class A consisting of those in whom no bacilli were found, the only physical signs being those of an apical catarrh; 1,245 belonged to this class, and of these 876 greatly improved, the lung signs disappearing; in 359 the physical signs persisted, but the patients were able to go back to work; and in 40 no improvement occurred; in all these last some complication was present. Class B, including those patients in whose sputum bacilli were discovered and in whom the signs of the disease were well marked, numbered 2,519; of these 1,047 were much improved, 1,171 were improved, 259 showed no change or were worse, and 6 died. In class C, including those cases in which either laryngeal phthisis or intestinal tuberculosis had been present before admission, there are 659 patients, and of them 198 are recorded as having improved greatly; 310 as having improved, 147 as not having improved, and 4 as having died. Class D comprised 729 cases in which the fever was persistent. Of these 106 patients greatly improved, 306 partially,

294 did not improve, and 23 died. On the strength of the above figures the author points out how essential it is that only early cases should be admitted to sanatoria, the only suitable cases being those in which there is a reasonable prospect of more or less complete cure.—*Quarterly Medical Magazine.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended July 20, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Illinois, Chicago	July 7th to 14th	2	
Kansas, Wichita	July 7th to 14th	2	
Louisiana, New Orleans	July 7th to 14th	11	5
Shreveport	July 7th to 14th	3	
Maryland, Baltimore	July 7th to 14th	1	
Massachusetts, Fall River	July 7th to 14th	1	
Nebraska, Omaha	July 7th to 14th	2	
N. Hampshire, Manchester	July 7th to 14th	1	
Ohio, Cleveland	July 7th to 14th	29	
Pennsylvania, Philadelphia	July 8th to 16th	1	
South Carolina, Greenville	July 7th to 14th	1	
Utah, Salt Lake City	July 7th to 14th	2	
Washington, Tacoma	July 1st to 7th	1	
Smallpox—Foreign and Insular.			
Brazil, Bahia	June 2d to 9th	2	
England, Liverpool	June 23d to 30th	3	
London	June 23d to 30th	16	
France, Lyons	June 16th to 23d	..	1
Paris	June 23d to 30th	..	4
Roubaix	May 1st to 31st	..	1
Greece, Athens	June 23d to 30th	4	2
India, Bombay	June 2d to 12th	..	12
Italy, Genoa	June 8th to 16th	3	
Mexico, Vera Cruz	July 1st to 7th	..	9
Scotland, Glasgow	June 22d to July 6th	170	3
Switzerland, Geneva	June 8th to 16th	1	
Yellow Fever.			
Africa, Goree Dakar	May 30th to June 16th	3	2
Colombia, Barranquilla	June 23d to 30th	9	6
Cartagena	June 22d to 20th	11	9
Cuba, Havana	June 27th to July 4th	..	5
Santa Clara	June 26th to July 7th	7	
Mexico, Cordoba	July 1st to 8th	Reported.	
Progreso	June 23d to July 8th	3	2
Cholera.			
India, Bombay	June 5th to 12th	..	72
Plague.			
Arabia, Aden	June 8th to 16th	3	3
Australia, Sydney	June 3d to 16th	14	6
India, Bombay	June 5th to 12th	..	117
Japan, Osaka	June 13th to 19th	1	
Shidzuoka	June 13th to 19th	1	

Non-Hygienic Gymnastics.—Mr. Buckham writes an interesting article on this subject in the current number of *Harper's Monthly Magazine*, some of which we here quote. From various competent sources we have received warning that the abuse of the body among athletes is increasing functional disease and shortening the average life of males. Suspicion that something was wrong first arose when it began to be observed that college athletes upon reaching middle life experienced in a majority of cases what has been called the premature decay of physical endurance. There seems to be among them a marked collapse of vital energy, a tendency to functional weakness and disorder, an inability to endure hard labor, either mental or physical. Men of slighter physical development who had not indulged in indoor gymnastics of the upside-down and violent type, retained, it was observed, at the same age with their formerly athletic fellows sound and active bodies and an unimpaired capacity for solid work. . . . Physicians have found in nearly all cases of vital exhaustion from excessive physical development enlargement and weakness of the heart with a tendency to acute heart disease. The lungs also seem often to have suffered some deterioration of cellular tissue, so that pulmonary consumption is not an infrequent disease with adult athletes. Generally speaking, the trouble seems to be a slow physical decay due to the early exhaustion of a vital energy which was intended to supply the body for seventy years or more, and to the disintegration of tissues which have been stimulated to abnormal development. Some physicians have gone so far as to pronounce this excessive enlargement of special muscles and parts of the body a diseased growth, something like a hard tumor, and they say that in the end the result will be the same as with other diseased growths—a pernicious anæmia. Indoor athletics—that is, gymnasium practice, especially when applied chiefly to the development of one set of muscles for competitive purposes—is extremely injurious from the fact that it is almost always carried to excess, and evidences its excess by the increasing malformation or disproportion of the body. The gymnast with huge shoulders and spindling hips and legs is a good and not infrequent example of the abuse of physical exercise. Anything like specialization in physical development ought to be strenuously avoided by one who wishes to retain throughout life a symmetrical body kept in perfect health by orderly and harmoniously exercised physical functions.

Athletics Barred from Chicago University.—The College of Physicians and Surgeons of Chicago after an animated debate has decided henceforth to refuse recognition to athletics, and no longer gives official sanction and support to the college football team, which has taken so prominent a part in intercollegiate athletic competitions. This step has been taken because experience has taught the faculty that college athletics have a demoralizing and disturbing influence on the students and interfere with the educational work of the college.—*Sanitarian.*

Books Received.

While the Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

CANCER OF THE STOMACH AND INTESTINES.

BY B. FARQUHAR CURTIS, M.D.,

PROFESSOR OF CLINICAL SURGERY AND ADJUNCT PROFESSOR OF THE PRINCIPLES OF SURGERY, UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

THE recent advances in surgery have much improved the results of operations for cancer, both by lessening the immediate mortality and by increasing the chances for ultimate cure. This paper will be limited to the consideration of cancer of the stomach and of the intestines, omitting the rectum.

A. According to Heimann's statistics collected from the general hospitals of Prussia in 1895 and 1896,[1] cancers of the stomach form twenty-one per cent. of all cancers. Of men afflicted with cancer the tumor is located in the stomach in thirty-two per cent., and of women so afflicted in thirteen per cent. it occurs in that organ.

The first question which arises is, whether operation offers a chance for cure of cancer of the stomach, and it is difficult to answer this question by any complete statistics. Wölfler, however, in his review of the subject for the German Congress of Surgeons in 1896,[2] was able to find fourteen patients who had been submitted to pylorectomy for carcinoma, alive and well two years after the operation, and ten others from four to eight years, making a total of twenty-four patients on record who remained well from two to eight years after the operation. These figures are certainly encouraging, and the fact that they are constantly and rapidly improving of late years indicates that before long we shall be able to state definitely the proportion of cases in which the patients are likely to remain well after the operation.

The second question is: What is the danger of resection for these tumors? Wölfler finds a mortality of thirty-one per cent. in one hundred and seventy-three operations performed by Billroth, Czerny, Gussenbauer, Kocher, Mikulicz, and others of the best German surgeons in recent years. Some operators have had a mortality of only twenty-five per cent., and some have had a series of many consecutive cases without a death owing to the improvements in technique. Carle and Fantino in fourteen cases lost only three, a mortality of about twenty-one per cent.

The next consideration is the decision as to what cases are suitable for the removal of the tumor without too great risk of life, and with a hope of effecting a cure. Some surgeons have laid down very strict rules for the limitation of the operation of resection of the stomach for these tumors, considering it justifiable only when the tumor is small without involvement of the glands and without adhesions—a limitation which would almost completely debar the surgeon from this operation. The cases of Schlatter, Richardson,[3] and others show that large tumors involving the entire stomach may be removed with an immediate successful result, and without serious interference with nutrition by reason of the loss of the organ, and that a reasonably long duration of life can be expected in such cases.

In the well-known case of Schlatter the patient survived in good condition for a year after the operation. The mere size of the tumor, moreover, is not an indication of such extensive involvement of the glands or of such extensive adhesions as to forbid operation, for several of these very large tumors have now been operated on and found free from both complications. In fact, this evidence shows that tumors of the stomach may reach a large size and involve a large part of the organ without forming such extensive adhesions as would prevent their removal, and without extensive infection of glands. We may, therefore, reject a limitation of the operation of resection based merely on the size of the tumor.

We may also reject the second limitation mentioned above—the presence of adhesions. The modern technique enables us to remove portions of the colon, of the liver, and even of the pancreas in these operations without seriously increasing the risk. In fourteen operations Carle[1] removed portions of pancreas in three cases. It might be thought that this secondary involvement of other organs would greatly increase the liability to recurrence, but some of these cases will be found among those of longest survival after recovery from the operation. There is, therefore, no reason for excluding these cases from operation, and there is even a chance for a radical cure if the patient's vitality is sufficient to bear the shock of the prolonged and complicated operation.

Finally we come to the restrictions imposed by the presence of enlarged glands in the neighborhood of the tumor. Even in this third and most serious limitation experience has shown that the same chance of error exists as in operations for cancer with enlarged glands elsewhere. The glands, although enlarged, may not be carcinomatous, and even when the glands are infected with carcinoma a wide removal may be successful, and may guarantee the patient against a return of the disease. The cases in which the glands are involved afford naturally the least prospect for a cure, but they are by no means hopeless. For instance, in four of his fourteen cases Carle found that the glands were enlarged, but examination after removal proved that they were not carcinomatous.

We must conclude, therefore, that no absolute rule can be laid down limiting the removal of these tumors and that each case should be judged upon its own merits, just as is done in cancer of the breast and of other organs. Here, as elsewhere, there will be favorable and unfavorable cases, and the surgeon must draw the line between them for himself, and must be allowed to remove the tumor even in the unfavorable cases if in his judgment such an operation is to the advantage of the patient by insuring him a longer life or greater comfort during his life. The fact is also to be noted that the majority of the patients who die from recurrence after pylorectomy not only enjoy a longer or shorter period of freedom from all symptoms, but ap-

pear to lose strength gradually, finally dying with less suffering than those who have not been operated upon.

If a patient with cancer of the stomach is to have any chance whatever of a cure by operation, and even a chance of coming through the operation of resection successfully, an early diagnosis of the condition is indispensable. To make this early diagnosis is really the principal difficulty in the treatment of these cases. Let us study the symptomatology of the disease. We may divide cases of cancer of the stomach into those with a tumor and those in which no tumor can be felt. When a tumor is present, it will usually be possible to determine its connection with the stomach by the usual methods of examination by palpation, distention of the stomach with air or water, and distention of the large intestine in a similar way. The tumor may even be discovered accidentally before any stomach symptoms have developed. It will be much more difficult, however, to determine whether the cases are so far advanced that even an exploratory laparotomy is not worth while, or whether there is still a chance for successful removal. As will be understood from the remarks previously made about the impossibility of placing strict limitations upon the radical operation, the writer would advise an exploratory laparotomy if the patient is in good condition, even if the tumor is of large size and somewhat fixed in the abdomen. It is impossible to determine the real condition of affairs without opening the peritoneal cavity and examining its contents.

The cases in which no tumor can be felt are much more difficult of diagnosis, and unfortunately this class includes a very large proportion of cases of cancer of the stomach. The tumor in the first stages may be very small, may be concealed under the ribs or adherent to the lower surface of the liver, so that it is impossible to reach it by palpation. In such cases the diagnosis must be made from the history, symptoms, and the chemical and other examinations of the stomach. From the history and symptoms one can only make a guess at the real nature of the case in the early stages, for characteristic vomiting is a very late symptom. The physical examination of the stomach can at best only show dilatation of the organ, and dilatation also is a late symptom. The modern methods of the chemical examination of the contents of the stomach are of much more assistance, although not absolutely reliable. In a general way it may be said that the majority of cases of cancer of the stomach show an absence or a great reduction of the quantity of hydrochloric acid normally present in the stomach contents. They also show the presence of lactic acid and a great reduction of the gastric digestive power for albumen. There is, furthermore, a decided impairment of the muscular function of the stomach, which results in retention of its contents, even if no stenosis of the pylorus be present. No symptom or group of symptoms, however, can be absolutely relied upon to prove the existence of a cancer, and very careful study of the signs found and all the symptoms of the case is necessary in every case. Some authorities (Hemmeter) lay much stress upon the microscopical examination of fragments in the washings of the stomach which may be detached by the friction of the eye of the stomach tube, and upon the presence of the Oppler-Boas bacillus in the stomach contents.

As an example of the manner of using these various signs, take a case with symptoms of stenosis of the pylorus: if in such a case the hydrochloric acid is increased, the stenosis is probably due to a benign cause; but if it is decreased or absent, the cause is probably malignant. If in any case there are no symptoms of stenosis, but the hydrochloric acid is reduced, a special study should be made of the motility of the stomach, and if this is found to be impaired, the probability is in favor of a cancer. It is by the intelligent use of these various symptoms in connection with each other that a diagnosis is to be made—not by blind reliance upon a single symptom or group of symptoms as pathognomonic of cancer. According to Hemmeter,[1] if rapid emaciation takes place in a patient with stomach symptoms, and it is found on examination that hydrochloric acid is absent and lactic acid is present in the contents of the stomach, while the power of digesting albumen has been reduced under thirty per cent. of the normal, and the Oppler-Boas bacillus is found, and if the patient shows no improvement after three or four weeks of medical treatment, one may be sure that carcinoma is present.

The whole aspect of the question of the treatment of cancer of the stomach has been revolutionized by the rapid modern development of the surgical treatment of the benign conditions of that organ. Formerly it was said that an exploratory laparotomy would not render the patient worse or immediately endanger his life if it should reveal a condition which could not be relieved by operation, or if the suspected cancer was shown not to be present. But now we may truthfully say that if no cancer is found it is probable that some other serious lesion will be discovered, which can be cured by operative methods, and which may be incurable otherwise. To give an idea of the possibilities of the surgical treatment of benign conditions of the stomach we may quote the report of Petersen from Czerny's clinic at Heidelberg,[2] in which fifty-five cases of pyloric stenosis, seven cases of gastric pain and vomiting, three cases of hæmatemesis, and one case of atonic dilatation were subjected to operation. The operations done consisted in the excision of gastric ulcers, pylorectomy, pyloroplasty, gastro-enterostomy, separation of adhesions, and divulsion of a narrow pylorus. We may also quote Carle and Fantino's report[3] on forty-one cases of operations for benign stenosis of the pylorus with dilatation of the stomach, including cases of spasm of the pylorus and of muscular atrophy of the stomach. In these cases pyloroplasty was done fourteen times, in three cases the pylorus was stretched, and in twenty-four cases gastro-enterostomy was performed. These reports claim good results and indicate how wide the field of surgical methods has become in the treatment of gastric disorders, supporting the assertion that if the exploratory laparotomy should show that the supposed carcinoma is not present the surgeon will probably find some lesion which he may treat successfully. In any case with serious gastric symptoms, therefore, the surgeon need not hesitate to advise an exploratory operation, even if there is only a suspicion of malignant disease. He is no longer forced to wait for a positive diagnosis, and, when that diagnosis is finally made, to find himself too late to be of service.

The modern indications for operation in cases of suspected malignant disease may be stated somewhat as follows: (1) The presence of a tumor; (2) dilatation of the stomach; (3) obstructive vomiting; (4) marked chemical changes in the gastric contents, even if other symptoms are slight; (5) hæmatemesis; (6) severe gastric pain. It will be seen that the above list of indications might lead to the discovery of benign as well as of malignant lesions, but in such a case a cure could be obtained the more easily and the operation would be the better justified.

With reference to one non-malignant lesion which occasionally simulates cancer—ulcer of the stomach—there is a special consideration to be noted. There can be no doubt that cancer is very often preceded by a chronic ulcer of the stomach, or develops directly

upon the base of such an ulcer. The evidence in favor of this view accumulates constantly. Rosenheim reported[1] that in fifty successive cases of cancer of the stomach under his care he found four cases in which there was evidence of a previous ulcer. He remarks that in all of these cases hydrochloric acid was present even in the advanced stages of the malignant disease. This would make eight per cent. of the cases of cancer of the stomach due to a preceding ulcer. Hauser, quoted by Boas, says that in five to six per cent. of the cases of carcinoma of the stomach the growth develops from an ulcer or the scar of an ulcer. Thiersch[2] was one of the early observers of these cases, but instances have multiplied much more rapidly recently. Karg[3] reports such a case treated by resection, and the patient was well (having gained fifty pounds in weight) three years later. Mikulicz[4] mentions five cases in which the symptoms were those of ulcer, but carcinoma proved to be present, as was shown in two cases by microscopic examination after resection, and in three by a truly malignant course after operation—one case of the latter being treated by excision and the others by gastro-enterostomy.

Mathieu[5] has recently reported three cases in which symptoms of ulcer of the stomach preceded the development of cancer by two, ten, and twenty-four years—by far too long to allow of the hypothesis that the disease was malignant from the first.

In three cases of my own the same condition existed, the symptoms previous to operation being as follows:

Case I.—William J. E——, steward on board steamship, twenty-eight years old, born in the United States, single. He was admitted to St. Luke's Hospital August 2, 1899. Members of the mother's side of his family are said to have had stomach trouble. He had all the diseases of childhood, and smallpox when a child. He has had no rheumatism, tuberculosis, or syphilis. He is very moderate in using alcohol; smokes considerably. He had exceptionally good health until the present illness began. In 1893 he had "bush fever" in South America. For ten years he has had constipation. The stomach symptoms began five years ago, with distress after eating and poor appetite, but sometimes he had a voracious appetite. Eructations of gas relieved the distress. Three years ago he began to vomit after eating, only two or three times a week at first, then oftener. He has never gone more than six days without vomiting since that time. Now he usually vomits two or three times a day, and a large quantity at a time. Once he says he brought up a gallon. He has noticed in the vomited matter food which he had eaten three or four days before. Mucus is present in the vomitus, but no blood or coffee-grounds material. The distress and pain are now less than they were six months ago. For eighteen months he has been using the stomach tube, evacuating and washing the stomach regularly. Fluids agree best with him. He was a hearty eater before his illness, but there is no history of overeating. He has lost fifty pounds in weight.

August 2, 1899, physical examination: The patient is a tall man of large frame, emaciated, weighing only one hundred and six pounds, but of good color, and with firm muscles. The heart, lungs, and liver are normal. The stomach descends to the umbilicus when distended, and its walls appear to be thickened. Its capacity is about fifty fluidounces. In the right hypochondriac region a tumor can be felt in the abdomen, about one and one-half inches in diameter, rolling upward and downward under the hand, and disappearing when the stomach is distended. The tumor is not tender or painful. Two small nodules can be felt on its surface. Chemical examination of the stomach contents after a test breakfast showed: hydrochloric acid much reduced, total acidity reduced. There is some mucus, no bile. Starch digestion is unusually good. There is some fermentation and acetic acid is present. Urine is acid, 1.020 specific gravity, with no albumin.

On August 5, 1899, pylorectomy was done by Kocher's method. There was an uninterrupted recovery. Twenty-three days after the operation he weighed one hundred and twenty pounds, and thirty-one days after one hundred and thirty-five pounds, having gained in that time just twenty-eight pounds. On November 5th he reports weighing one hundred and sixty-eight pounds, able to eat everything except fruit and the more fibrous vegetables.

The pathologist of the hospital reports that the tumor is a pure carcinoma, in spite of the very long history of pyloric obstruction.

Case II.—Louisa K——, twenty-eight years old, married, born in Germany. She was admitted to St. Luke's Hospital July 31, 1899. Family history is negative. The patient had measles and mumps in childhood. Four years ago she had some internal operation for uterine displacement (?). Considers her health previously good. The menstrual function was normal. She has been married four years, and had one child born fifteen months ago (now dead), with normal labor and convalescence. After birth of the child she had dull pain in the epigastrium and the left inguinal region after eating, with some nausea. She brought on vomiting by tickling her throat with her finger, and sometimes saw blood in the vomited matter, which was watery and slimy. She has been seriously affected about three months. Her appetite is good except when pain is present. She has had left lumbar pain, sometimes worse after eating. The bowels are regular. Her principal complaint is the lumbar pain, which occasionally radiates to the shoulder. She has not noticed the tumor.

Physical examination: The patient is of medium frame, fairly nourished, and appears anæmic. There is a slight systolic cardiac murmur over the base. The lungs are normal. The abdomen is generally tense. A hard tumor about half as large as the fist can be felt just above and to the left of the umbilicus, apparently attached to the rectus mucle. The tumor is tender on pressure and dull on percussion. Distention of the colon reveals it lying below and partly beneath the tumor, below the level of the umbilicus. The stomach appears to descend to the umbilicus. The tumor can be moved when the abdomen is relaxed, but is immovable if the muscles are tense. It does not move with respiration. The mass appears rather flat, and there are no nodules to be felt. It cannot be felt in the loin. The liver can be mapped out one inch below the edge of the ribs. The genitals are practically normal. The temperature was practically normal up to the date of operation, occasionally reaching 100° F. The bowels were regular. The urine was acid, specific gravity 1.018, containing a few pus cells and epithelial cells. There was some nausea (perhaps due to iodide of potassium given experimentally) and sufficient pain to make the patient sleepless. There were 14,000 leucocytes. No examination of the stomach contents was made. An exploratory incision was determined on.

On August 12, 1899, the operation was performed under ether anæsthesia. A vertical incision was made directly over the tumor through the left rectus muscle. The latter was found infiltrated and the peritoneum thickened over an area about two inches in diameter, and the stomach was adherent at this point. The anterior stomach wall was thickened to a full inch. After separating the adhesions, a small but very hard

apparently carcinomatous gland was found above the ulcer on the lesser curvature of the stomach. The thickening in the stomach extended almost entirely across the anterior wall of the stomach near its middle, leaving the pylorus free with about two inches of healthy stomach between it and the mass. Resection was decided upon and carried out on the same plan as in the first case—Kocher's method with use of the Murphy button. In this case, however, the portion of stomach removed measured five inches across. The lower line of excision passed through the stomach one inch from the pylorus, the upper about two inches from the œsophageal opening (on the lesser curvature). The stomach was dilated, hence the remaining organ after the operation was about half the size of a normal stomach. There were no adhesions except those described, and no other glands were found enlarged. Examination of the piece removed was made, and an ulcer nearly three inches in diameter was found, with an immensely thickened base. The posterior wall of the stomach was healthy. The stomach contained a dark red, thick fluid of intensely fetid odor. A little pus formed in the wound, apparently originating in the abdomen, but caused no rise of temperature or pain. It was discharged on the eleventh day, and the opening healed by granulation. The patient felt no hunger until about two weeks after the operation. She was not weighed until the thirty-second day after the operation, and then weighed eighty-seven pounds. She weighed one hundred and five pounds three weeks later. The pathologist reports carcinoma in the tumor and in the lymphatic gland removed.

(Cases 1 and 2 are quoted from the report in the *Yale Medical Journal*, January, 1900.)

Case III. (shown to New York Surgical Society February 28, 1900).—Julia C——, thirty-eight years old, married; employed at housework; born in United States. Admitted to St. Luke's Hospital October, 1899. She was never pregnant, and had enjoyed previous good health. Four years before admission she began to be troubled with eructations—"heart-burn." Her symptoms increased, but there was no actual pain in the stomach. Nausea and vomiting set in two years before admission, and gradually the vomiting became so complete that only fluids were retained, and the patient lost ninety pounds in the last year. She now weighs only one hundred and twenty pounds, although of large frame. Six months and three months ago, and again lately, she has had attacks of "coffee-ground" vomiting. A small tumor was felt at the pylorus. Examination of the stomach contents showed the hydrochloric acid slightly diminished, lactic acid absent, and digestion of proteids reduced.

On October 28, 1899, pylorectomy was done by Kocher's method. In the portion removed an ulcer two and one-half inches in diameter was found on the anterior wall, with a greatly thickened base, the latter having occasioned the pyloric stenosis as it extended to the pyloric ring. The patient made a good recovery, and on March 5, 1900, weighed one hundred and sixty pounds, being able to eat everything. The pathologist reports that the base of the ulcer is carcinomatous, but some enlarged glands removed with the tumor were free.

It is not surprising that the frequency of the association of chronic ulcer and of carcinoma has not been brought out sooner. When the study of carcinoma of the stomach depended upon post-mortem examination, or even upon operations performed in cases with well-developed tumors, it was impossible to say if any other pathological changes had preceded the malignant disease, for the latter would by that time have destroyed any evidence of the previous lesion. It was only with the development of the modern methods of diagnosis in stomach diseases, and especially of the modern surgical treatment of benign lesions of the stomach, that the coexistence of an ulcer and a beginning carcinoma was likely to be discovered. The clinical history will show more often than has been realized that a grave lesion of the stomach must have preceded the cancer by years. But this history cannot be relied upon entirely, for many cases of chronic ulcer run a latent course like those described above, and give no sign until pyloric stenosis develops.

The practical outcome of these consideration is that every patient who gives evidence of serious stomach trouble should be carefully studied and an accurate and early diagnosis made if possible. This study should include a careful physical examination of the abdomen, in order to determine the presence or absence of a tumor, and the outlines of the stomach and colon should be ascertained by distending these organs with air or water. It would also include a chemical examination of the stomach contents and a microscopic examination of the solid particles found in the washings. With a little tact patients can be induced to submit to the use of the stomach tube and the necessary manipulations. We are not doing our duty if we prescribe medical treatment which will merely relieve the most urgent or annoying symptoms—rather should we use those symptoms to persuade the patient to undergo a thorough examination. To neutralize the acidity of the stomach with alkalies, relieve the pain by anæsthetics, or control the vomiting by fluid diet in such cases, without trying to discover the cause of these symptoms, is not merely foolish temporizing, it is criminal neglect.

If the indications for operation mentioned above—the presence of a tumor, vomiting, dilatation of the stomach, or chemical changes—are found, operation should be advised even if the diagnosis is not altogether certain, in the expectation that an exploratory operation will not merely settle the diagnosis, but will probably reveal some definite lesions which can be relieved by surgical procedures. These indications for operation are worthy of consideration even in cases in which the symptoms are not very serious, but are obstinate, and persist in spite of thorough treatment by drugs, diet, and lavage. If the diseases have advanced too far for a chance of cure by radical operation, it may admit of palliative measures, such as gastro-enterostomy, which will prolong life and make its end less distressing. Even if the case is one of very long duration and seems unfavorable for a radical cure, there is still a possibility that the laparotomy may reveal a condition in which thorough extirpation of the tumor may have some chance of permanent success. Streit[1] reports fifty-four cases of cancer of the stomach examined post mortem in which he found that even at that late period, when the disease had caused death, the local conditions would still admit of successful resection in twenty-five per cent. of the cases.

Gastro-enterostomy has its limitations as well as resection. Heimann[2] found that about fifty per cent. of the cases of cancer of the stomach submitted to operation in Germany in 1895 and 1896 were treated by gastro-enterostomy. Gastro-enterostomy overcomes the consequences of the obstruction of the pylorus or of dilatation of the stomach through muscular atrophy. The operation acts by providing a free outlet from the stomach and by accomplishing drainage of the large pocket formed by the dilatation. It has, therefore, two favorable effects—first it improves nutrition by enabling the food to pass on into the intestine for absorption; and, secondly, it drains the stomach and thus limits the fermentation and lessens the absorption of poisons produced by this decomposition. The performance of gastro-enterostomy, however, will have

[1] Deutsche Zeitschrift für Chirurgie, xxvii., 410.
[2] *Loc. cit.*

little or no effect when pain is the prominent symptom of the cancer, for the reason that the pain seldom if ever originates in the stomach itself in these cases, but is generally due to the pressure of the enlarged retroperitoneal glands on the nerves, and is naturally not affected by drainage of the stomach. There are certain other contraindications to gastro-enterostomy, namely, such excessive weakness of the patient as to make death probable from the shock of the operation, and such extensive disease as to leave no point free at which the outlet can be made. Wölfler[1] found in one hundred and forty-nine cases of gastro-enterostomy performed for cancer, collected from the German clinics, a mortality of thirty per cent. The longest survival after operation was two and one-quarter years, the average interval before death being only six months. Murphy reported[2] sixty-one cases operated upon by his button method, with a mortality of forty-six per cent., but this is a list of all recorded cases and should not be compared with Wölfler's series, selected from certain first-class clinics.

The weak condition of patients with cancer explains the high rate of mortality—certainly three times as great as the mortality of the same operation performed for benign lesions of the stomach. It also explains why the palliative operation has almost as high a rate of mortality as the operation for the removal of the tumor, for resection is undertaken only in patients in the earlier stages of the disease, who are in much better condition than the average patient submitted to gastro-enterostomy. Yet in spite of the high mortality the operation is well worth the danger it involves, for it relieves the patient of the harassing vomiting and the sensations of starvation, and obtains for him a much more comfortable and gradual sinking of his strength without seriously annoying symptoms.

B. **Carcinoma of the Intestine.**—Not long ago carcinoma of the intestine and of the stomach would have been classed together from a clinical point of view, both occurring in organs consisting of a muco-musculo-peritoneal canal containing digestive material, and differing only in the more active chemical changes of the upper end toward the stomach and in the more active bacteriological life of the lower part. They have now, however, assumed very different positions, because the advances made in the chemical examination of the contents of the stomach have rendered much assistance in the diagnosis of the gastric lesions, while our knowledge of intestinal diseases has not progressed so far. Malignant tumors of the intestine, with the exception of those in the rectum, are quite rare. According to Heimann, 8.5 per cent. of all cancers occur in the intestine, but nearly three-quarters of these are situated in the rectum. The scope of the present paper does not include the lower rectal tumors, as they should be studied rather in connection with pelvic disease, or with external tumors, but the tumors higher up in the rectum have the same characteristics as those of the sigmoid flexure. Sarcoma of the bowel is rare, nearly all its malignant tumors being carcinoma. The sarcomata are found more frequently in the small intestine than in the large, but are so rare as to be of little surgical importance. Primary carcinoma of the small intestine is also rare, the great majority of these tumors occurring in the large intestine. Even in the large intestine there are certain portions in which the tumors are especially likely to grow, the most common situations being the sigmoid flexure, the splenic flexure, and the ileo-cæcal region.

Carcinoma of the large intestine is found in two very different varieties. In the first variety tumors of a considerable size are formed, and such tumors are apt to be of colloid material. They are most frequently found in the neighborhood of the ileo-cæcal valve, but do not obstruct the passage of the bowl materially in spite of their size.

The other form is the annular tumor, which is far more common than are the large colloid masses. The annular tumor contains a large proportion of fibrous tissue in its structure and the intestinal wall involved in it is contracted, so that instead of producing a tumor-like mass, the diseased parts are actually smaller than before. These annular growths invade the epithelium first, spreading in a ring-like manner round the inner surface of the bowel, and the multiplication of the epithelial cells is accompanied by an abundant growth of connective tissue, forming a dense fibrous stroma. Its growth is slow, the epithelial changes invading the healthy tissues at the edges of the annular lesion, and spreading upward and downward, constantly widening the annular band. The connective-tissue stroma in the submucous coat contracts and cuts off the blood supply at the centre of the lesion, causing a tendency to sloughing in the epithelial cells and the production of a ring-like ulcerated surface in the centre of the annular band. Where the ulcer is deepest there are few epithelial cells, its base being mostly formed of fibrous tisue, with a granulating surface. The central portion of the growth continues to contract by virtue of the cicatricial property of the fibrous tissue and makes an annular stricture of the bowel at this point, which projects internally into the lumen like a diaphragm, while externally it forms a groove by drawing the outer coats of the bowel inward, with the appendices epiploicæ and the mesentery. At this stage the outside of the bowel appears on inspection to have had a constricting thread tied tightly around it, making a groove which is almost concealed by bunches of fat made up of the appendices and mesentery, which are drawn toward it. When the affected bowel is palpated, a small hard thickening is felt in its wall, which is the annular growth, but if any considerable tumor is present, the bulk of the mass is made up of the appendices and other parts drawn into it by its contractile power, and not of the new growth itself. A longitudinal section of the bowel shows very clearly the narrowing of its lumen by the drawing in of all the coats as if by this imaginary thread.

The epithelial growth is so slow that the width of the annular lesion may not be over an inch, although symptoms of constriction have been present for a year or more.

Equally slow is the glandular involvement. Lardenois[1] calls attention to the arrangement of the lymphatics, as shown by Sappey's dissections, which explain both the peculiar form of the growth and the slow glandular involvement. The lymphatics of the intestine may be divided into a submucous and a subserous set. Sappey states that both sets run circularly around the bowel like the blood-vessels, and discharge into small nodes at the mesenteric attachment. There is comparatively little communication between the two sets of lymphatics. Having entered the small lymphoid nodes at the mesenteric border of the bowel, the lymphatic vessels issue from them unchanged in size, form a reticulum along the mesentery, and then pass through another set of nodes near the first before reaching the larger lymphatic glands at the root of the mesentery. Any material which may enter the lymphatics must pass through three lines of defence—the small nodes at the attachment of the mesentery, the second row beyond, usually known as the "mesenteric glands," and finally the retroperitoneal glands at the root of the mesentery, before a general infection can take place. We frequently find the glands entirely free or the infection extending only to the first row of glands in cases in which it is evident from the size and connec-

[1] *Loc. cit.*

[2] Medical News, February and November, 1895, pp. 141, 533.

[1] "Traité de chirurgie du cancer du gros intestin," Paris, 1899.

tions of the tumor that it must have been in existence for a long time. This slow extension is also evidenced by the fact that patients have remained well for long periods after the removal of a tumor with glands shown to be carcinomatous.

In many of the malignant growths of the bowel the minute structure is often misleading in its character, as it is marked by a very exact reproduction of the tubular glands of the intestinal mucous membrane, with very little or no tendency of the epithelial cells to penetrate the basement membrane and infiltrate the fibrous stroma. The minute structure even in the late stages is often that of an adenoma rather than of a carcinoma, and this fact may also partially explain their slow course. But, in spite of these benign characteristics, the tumors are exceedingly likely to return after removal unless widely excised, and at every recurrence the tumor becomes more malignant. A considerable number of cases are on record in which multiple polypi of adenomatous structure have preceded the development of the more malignant growth.

Malignant tumors of the bowel are almost always single, but a few cases are on record in which multiple carcinomatous strictures of the large and small intestine existed, and Kuttner has reported [1] a case in which as many as twenty-two strictures were found. In a case of Körte, after removal of a tumor from the sigmoid flexure the patient died from intestinal obstruction, caused by a second annular carcinoma at the splenic flexure.

As is the case with the similar tumors of the stomach, the symptoms and course of carcinoma of the intestine are largely, and sometimes entirely, the result of the mechanical obstruction of the bowel, occasioned by the new growth. The patient may have chronic constipation, occasionally developing into attacks of complete obstruction, and this is sometimes accompanied with violent attacks of colic. In other cases the bowels move regularly, and the patient is not aware of any disturbance of his health, but suddenly acute obstruction sets in, and when the abdomen is opened, the local examination shows an annular growth in the bowel, with an opening through the stricture so narrow that a cherry pit, or even an apple seed, is sufficient to plug it, and it seems marvellous that so close a stricture could exist for so long a time without symptoms. Probably in these cases the muscular hypertrophy of the bowel above the tumor, with unusual fluidity of the intestinal contents, has been sufficient to maintain the passage through the stricture until it has been suddenly plugged by the foreign body.

In some cases the stagnation of the contents of the bowel above the stricture may give rise to an ulcerative inflammation with a discharge of muco-pus in the stools and a tendency to diarrhœa. This ulcerative process may also cause a localized peritonitis or an actual perforation of the bowel, resulting in general peritonitis or in the formation of a local abscess. Metastatic abscesses of the liver or elsewhere may also be the consequence of this ulceration of the bowel, and death may result in this indirect manner. According to Treves,[2] blood is to be found in the stools in fifteen per cent. of these cases, but hemorrhage is usually a late symptom, and indicates an ulcerated tumor, rather low down. In very rare cases the stricture has completely closed the bowel and caused its rupture above with fatal peritonitis, or an anastomotic opening has formed after adhesions had united a loop of bowel above the stricture with a loop below it.

It may truthfully be said that intestinal cancer affects the health and causes death chiefly by the purely mechanical obstruction of the bowel which it produces, or by some consequence of that obstruction, such as ulceration and pyæmia, or perforation and peritonitis. In some cases, however, the obstruction is not complete, and then death is caused by a cachexia, brought on by changes in the blood, metastasis in vital organs, or such complete involvement of the mesenteric glands and the liver as to impair the digestion and absorption of food. From these facts it results that an early diagnosis of carcinoma of the intestine is seldom, if ever, to be made, but that in spite of this difficulty even late operations may effect a permanent cure, or at least greatly prolong the patient's life.

The diagnosis of cancer of the bowel is to be made from obstinate chronic constipation, or constipation which alternates with diarrhœa. But it should also be remembered that chronic diarrhœa, with a mucopurulent discharge, may be the sole symptom, with no tendency to constipation. Attacks of intestinal colic, with more or less intestinal obstruction of a subacute type, which yield to medication, the attacks of colic growing more severe and becoming more frequent as the case advances, form another common clinical picture. These attacks may progress almost to complete obstruction, and yet finally yield to medical treatment. True fecal vomiting is not very common on account of the low situation of the obstruction. Occasionally blood or pus will be found in the stools. Very seldom can reliance be placed upon stools of ribbon or pill-like shape, for there are many other conditions besides stricture of the intestine which cause the fæces to take this form. In some cases a tumor may be felt in the abdomen or upper rectum, and the rectal and vaginal examinations should never be omitted when a tumor of the intestine is suspected. Some tumors of the sigmoid flexure can be discovered only by bimanual palpation in this manner. The significance of these symptoms will be greatly increased if the patient is forty years of age or older, and if he has been losing weight, growing pale or yellowish, and has vague symptoms of indigestion, such as pain, tendency to nausea, etc. A tumor will often be discovered accidentally before any other definite symptoms develop, and such cases are the most fortunate, for in them the indication for operation is the clearest.

The indication for operation is equally urgent, however, if the patient presents a history of constipation (with or without diarrhœa at intervals) and has severe recurrent attacks of colic, with obstruction, such as described. It is not enough to treat such patients by drugs and diet, although they may be made comfortable by that course, and the attacks may be rendered less frequent. What has been said in regard to those who suffer from severe gastric symptoms is also true of patients with symptoms indicating even slight obstruction of the intestine: we must devote the greatest possible care to the study of these cases in order to determine at the earliest possible moment the presence of malignant disease. Every patient with such symptoms should be thoroughly and repeatedly examined by palpation of the abdomen and by the rectum, for one examination, or even several, may prove futile, and yet finally the tumor may come under the surgeon's hands. Some of these tumors are so small and so movable that it is difficult to recognize them unless they are actually pressed between the fingers and the posterior abdominal wall. The patients are liable to an accumulation of gas in the intestines, which materially interferes with the examination. The diagnosis of chronic constipation so often entered upon our case books should be given up, and a more scientific recognition of the causes of constipation substituted for it. A certain number of cases, in which no tumor has been recognized, will come to the surgeon at a late period because of intestinal obstruction or perforation of the bowel, with general peritonitis, or the formation of an abscess. In

[1] Beiträge zur klinischen Chirurgie, xxiii., Hft. 2.
[2] "Intestinal Obstruction," chap. xiii.

1892 I was called to operate for an intra-peritoneal abscess developing in an Irishman sixty years of age, who had been ill only two days and a half. Two or three ounces of pus were discharged through an incision over the tumor, near the middle line below the navel. A sinus persisted, and there was deep induration surrounding it, and in 1894, when I accidentally saw him again, he had a large mass of new-growth, half filling the abdomen, and was emaciated beyond recognition. Of the other type of acute or subacute obstruction of the bowels, coming on while the patient was in apparently good health and due to sudden plugging of a carcinomatous stricture of the bowel, I have seen several cases, all of them in the sigmoid flexure.

I need not dwell here upon the various points upon which to rest the diagnosis of the situation of tumors of the intestine, but merely remark that the diagnosis of the exact seat of the lesion can be made in a certain number of cases if pains be taken in the examination. In cases in which no tumor can be felt, but recurrent attacks of colic or subacute intestinal obstruction are present, or in which there is chronic constipation to an extreme degree (with or without diarrhœa), exploratory laparotomy is justified. It is true that there are many benign conditions which may cause these symptoms, such as peritoneal adhesions and bands, kinks or volvulus of the bowel, pressure upon the gut by inflammatory masses, enteroptosis, and so on, but the great majority of these conditions can be relieved by surgical treatment, and often can be benefited by no other means.

The surgical treatment of carcinoma of the intestine consists in radical removal of the tumor, or in merely relieving the obstruction without attempting to remove the tumor. The mortality of resection of the intestine is serious, but it is constantly being reduced, and in simple cases should hardly exceed that of pylorectomy. Wölfler gives thirty-three per cent. as the mortality of the same set of surgeons upon whose stomach work he reported. This high mortality is due to including in the lists many cases of very large tumors the removal of which was very difficult, and also some cases in which resection of the intestine was undertaken when acute obstruction of the bowels was present and the patient was in very poor condition. Schiller has lately reported a series of cases from Czerny's clinic, with a mortality of fifty per cent. In this series three patients remained well respectively for ten, five and a half, and three and a quarter years, three patients remained well for fourteen to sixteen months, and still continued under observation. Thus three patients remained well for over three years out of the ten who survived the operation. Wölfler reports fifteen patients who remained well from one and a half to three and one-half years, seven remained well for four years, two for six years, and one for seventeen years. These were principally cases of carcinoma of the large intestine.

The mortality varies greatly with the part of the bowel removed, and especially with the cause for the operation, resection of the cæcum giving the best results. Czerny had eight and Körte nine resections at this point with only one death. The mortality of resections of the bowel for tumors is much greater than that of the same operation for other reasons. Körte has recently reported eighteen cases of resection for tumor, with only six deaths; there were six cases of tumor of the ileo-cæcal portion, in all of which the patients recovered, one patient living eight years and two patients living five years without recurrence. In six cases the tumor lay in the transverse colon, and only two patients recovered, one remaining well five and one-half years. The remaining six cases were of tumors of the descending colon and sigmoid flexure, in which four patients recovered, remaining well respectively for two and one-half years, one and one-half years, one-half year, and in one case for an unknown period. I have quoted these figures fully because they give some idea of the chances of recovery from operation and for obtaining a radical cure.

The palliative operations consist in the formation of an artificial anus or the making of an anastomosis between the bowel at a point above and below the stricture, to which latter operation may be added the so-called exclusion of the diseased part of the bowel. The formation of an intestinal anastomosis will often enable us to dispense with the inconvenience of an artificial anus, but neither this operation nor resection should be attempted in the presence of acute obstruction. When the obstruction of the bowel is complete, or nearly so, and the patient is in poor condition, the only proper method of treatment is at once to relieve the obstruction by the formation of an artificial anus, leaving the treatment of the tumor to a later period. This should be placed preferably in the left groin, for an opening in the cæcum is apt to be more troublesome, because the greater fluidity of the contents increases greatly the difficulty of their retention. A lumbar colostomy on the left side would be preferable to opening the cæcum, if one could be sure that the point of stricture lay in the sigmoid flexure. Even if the tumor cannot be removed great relief may be afforded and life may be indefinitely prolonged without serious discomfort by the artificial anus, and it should be made in every case as soon as symptoms of obstruction present. Modern methods of forming the artificial anus render it possible to make it sufficiently tight to control solid fæces, sometimes even providing a sphincter-like action of the fibres of the abdominal muscles around the opening, so that life becomes quite bearable.

The newer operation of intestinal anastomosis fulfils the same indication as an artificial anus, for it relieves the obstruction, and it might be almost termed an internal anus. It is suitable for many cases of tumors of the intestine which cannot be removed, but, as I have said, should not be undertaken in the face of acute intestinal obstruction. The external anus should be made first and the intestinal anastomosis done as a secondary operation, the artificial anus being then allowed to close. The bad condition of the intestinal wall renders it dangerous to make an opening in the bowel above the obstruction when it is acutely distended. Wölfler reports the mortality of intestinal anastomosis to be thirty per cent., but Marwedel has reduced his mortality for this operation to twelve per cent.

Attempts have been made to shut off entirely the diseased part of the bowel—the operation called "exclusion of the intestine." In this operation an intestinal anastomosis is made between the bowel above and that below the point of stricture, and the bowel is then entirely divided above and below the tumor between the latter and the anastomosis. One end of the diseased bowel must be attached to the abdominal wound, so as to admit of the escape of its discharges, and the other closed if desired. Wölfler reports twenty-two cases of this operation performed for various conditions, not merely for cancer, with three deaths, a mortality of fourteen per cent., but undoubtedly the mortality for the cases of malignant disease alone would be somewhat higher. The advantages claimed for this modification of the operation of anastomosis is that it will keep the fecal matter from contact with the tumor and lessen the liability to ulceration, while it will allow external escape to the discharges without interfering with the normal bowel below. It is as yet uncertain what is gained by this method of treatment, and more experience is necessary before passing judgment upon it.

The operation of intestinal anastomosis has one disadvantage as compared with the artificial anus. In the latter operation it is possible to select a point in the bowel far away from the tumor and not likely to be invaded later by the disease. In intestinal anastomosis the point of anastomosis is apt to be near the diseased part of the bowel, and in a considerable number of cases it becomes involved in the disease later. In two cases of my own, however, the patients lived for five months and eight months after the anastomosis was completed, dying of cachexia, without any further obstruction. In both cases the tumor was in the sigmoid flexure, and the anastomosis was made between a loop of the sigmoid just above the tumor and the upper part of the rectum.

I have no better statistics to give for the duration of life after an artificial anus than Bryant's,[1] who in one hundred and nineteen cases found that thirty-six died in the first year, forty-three in the second, and twenty-six in the third, while twelve lived from three to six years after the operation. Probably the results of intestinal anastomosis would be nearly the same, but with a higher mortality and a greater liability to renewed obstruction.

HYDROTHERAPY IN PNEUMONIA.[2]

By SIMON BARUCH, M.D.

NEW YORK.

A glance at the treatment of acute diseases during the past half-century reveals the fact that a revolution has taken place, which has culminated in the practical abolition of the treatment of these diseases. In our own country this revolution was initiated by Jacob Bigelow, a former member of this society, by his work on the "Self-Limitation of Diseases," published in 1835, and by his later work on "Nature in Disease." Re-enforced by the good sense and captivating eloquence of your Oliver Wendell Holmes, American medical men have been slowly—alas, too slowly!—changed from destructive to constructive therapy. We realize to-day that, with few exceptions, the manifestations of disease are but the outward expression of pathological conditions which no remedial agent is capable of removing. This proposition will not be construed by any fair mind as an abandonment of the patient to his fate, it simply emphasizes the fact that we no longer attack the disease by violent medication, as was formerly done by bloodletting and mercury and blisters, later by veratrum and aconite, and more recently by antipyretics. If the symptoms of disease were really the essence of disease, our complete control of the pulse by veratrum, of temperature by antipyrin, of sleep by chloral, of pain by morphine, of feebleness by the modern foods and stimulants would to-day insure our triumph over disease. The fact that, despite the response of the most significant symptoms to these powerful agents, the patients continue to succumb, has awakened the medical conscience to a realization of the truth of the doctrines taught by your Bigelow, Holmes, and Hooker sixty or more years ago—that the patient rather than the disease must be treated.

In a malady like pneumonia, bloodletting, mercury, and other spoliative agents relieved pain, softened the pulse, and lulled the doctor into a false security from which he was too often rudely awakened when heart failure presaged the approach of the end. The old spoliative practice was abandoned when practical men discovered that it robbed them of the chief ally in the campaign against the disease—the vis medicatrix naturæ.

If you reflect that for two thousand years the medical profession labored under the fatal error of fighting disease, while the patient, being the battle-ground, suffered from friend and foe alike, you will bear with me in paying a tribute of gratitude to the man who courageously blazed a pathway through the confusing mazes of spoliative medication to "Nature in Disease." I esteem it a high privilege to announce here amid the very scenes of his professional activity, that, like Jacob Bigelow, I trust to "nature" in pneumonia and in every other acute disease. Not blind, as that of the Christian Scientist in prayer and faith, is my reliance on nature, but ready in armed expectancy, to intercede in her behalf when peculiarities of the patient, or the disease, or condition of environment point to a deviation from normal processes of restitution. Isolation, rest, cleanliness, ventilation, food, drink, and if need be medication, should be so directed as to enhance the resisting-capacity of the patient—so to fortify him that his inherent powers have free play in eliminating the noxious products which threaten to overwhelm him.

Among these agencies I esteem hydrotherapy as one of the most valuable. The application of water is not a curative agent for pneumonia, but its judicious use has afforded me much comfort, and has doubtless contributed greatly to the diminution of mortality.

A somewhat active professional life of nearly forty years, spent in country, village, city army, family, and hospital practice, has brought me to the conviction that pneumonia is an infectious disease, which tends to destroy life by enfeebling the nervous and circulatory systems, and that the indications for overcoming this lethal tendency are (1) To fortify the nervous system; (2) to sustain the heart, whose integrity is of vital import in overcoming the local lesions and in removing inflammatory products by a vigorous circulation, (3) to strive for elimination of noxious products arising from the life and death of the diplococcus; (4) to render the patient comfortable by reducing high temperature, deepening inspiration, and producing sleep.

Flexibility is a notable quality of hydrotherapy. By various procedures, and by changing temperature and duration, we may adapt the application of water to the most opposite conditions. In no disease is this better exemplified than in pneumonia. Although its general manifestations resemble in many respects those of typhoid fever, its local manifestations differ from the latter as the Eberth bacillus differs from the diplococcus of Fraenkel. While in typhoid fever the cold bath, preferably as suggested by Brand, has proved of surpassing value, such a bath is not adapted to a patient suffering from pneumonia. The reason is clear at the bedside, the typhoid patient resists temperature abstraction with much tenacity, the pneumonia patient as a rule quickly responds to heat abstraction This clinical fact has often enabled me to confirm a tentative diagnosis, especially in children up to sixteen years.

While the typhoid patient, as a rule, bears the disturbance involved in tub bathing fairly well, such a procedure is extremely distressing in pneumonia by reason of dyspnœa, cough, and pain Although Vogl, of Munich, Folsom, of Boston, and others have reported good results from cold full baths, I have abandoned them with adults for these reasons In the pneumonias of young children who are easily lifted, I still use full baths of moderate temperature (95°–80° F.), or cold affusions with water of lower temperature (70°–60° F.) in severe broncho-pneumonias with bronchial obstruction, because in these cases pleurisy

[1] "Colotomy." Wood's Med and Surg Monographs, New York 1890, vol. vii.

[2] Part of a symposium on pneumonia before the Massachusetts Medical Society

is usually absent, and the shallow breathing and deficient oxygenation due to bronchial obstruction are greatly relieved by the agitation, crying, and coughing incident to the full bath, with friction. It is my rule in all cases to be present during the first bath, even in consultation cases when practicable, in order to note the reaction and obtain other information for further guidance, because individuals differ materially in their response to bathing. While each case demands more special study with regard to baths than to other remedies, I usually begin with a tub bath (given alongside of the bed) of five degrees below the patient's temperature, and diminish the baths two or three degrees at each repetition every four hours, until 80° F. is reached. The child's head and face are bathed in water at 65° F. before entering the bath, and gentle friction is made over the body during the entire bath. During the intervals between the baths the following method pursued with adults is adopted. In the latter I have for reasons stated above substituted the wet thoracic compress for the full bath. It is my custom to have the rectal temperature taken every hour when the patient is not asleep. So long as the thermometer registers over 100° F., a compress made of three folds of old coarse linen, wrung out of water at 60° F., is wrapped around the chest from the clavicle to the umbilicus. It should be long enough to lap over one inch in front, and so slit in its axillary portion that it may rise easily up to the clavicles without leaving rough folds in the axilla. This compress is smoothly wrapped around the chest and covered by one layer of thin flannel, one inch wider and longer.

The effect of such an application of cold is so readily observed that it would seem needless to dwell upon it, did not so much misapprehension exist in the average medical mind on the object of cold applications in febrile disorders, that it is necessary to define it again and again, to remove these erroneous impressions. Pardon me if I advert to some familiar physiological data. We know that cold and heat are thermic irritants which stimulate when mild, depress when more severe, and destroy vitality when sufficiently intense. Applied through the medium of water and regulated with regard to temperature, duration, and mechanical impact, we may so modify these thermic impressions as to produce therapeutic results for which we look in vain in other remedies. The primary effect of cold is that of an irritant to the peripheral sensory network of the skin. This has been called shock, an error which is evident on reading the definition of shock in Gould's dictionary, which is "depression, a grave effect produced by severe injuries, operation, and strong emotion." To produce shock with cold water, it would be necessary to put the individual into a tub of water very much below the body temperature, and sufficiently long to prevent reaction. If the water be near the freezing-point, and he could not escape, the individual would become unconscious and the vitality of the skin would be destroyed, if he survived long enough to suffer from frostbite. Bear in mind that the same effect would be produced by hot water, under similar conditions; and yet no one ever speaks of the shock of hot water. The truth of the matter is—and I trust you will pardon my offering so simple and familiar a proposition—that cold stimulates when mild and shocks when it is intense, and upon this principle we stimulate the nerve centres in pneumonia. A compress containing water at 60° F., when applied around the chest of a patient having a temperature 40° F. higher, produces an irritation of the sensory filaments in the skin, which is conveyed to the central nervous system and thence reflected upon the organs receiving impulses from the latter. This is plainly evidenced by the patient's momentary gasp, the heightened pulse tension, the deepened and slowed inspiration, and the lowering of temperature. By changes in the preparation of the compress, we may positively modify its effects. If, for instance, the body temperature is not very high, say from 100° to 102° F., the compress may be more thoroughly wrung out, so as to make the impression of cold more brief, reaction more rapid and less enduring. If the temperature be high, 103° F. or above, the water temperature may be raised to 95° F., and more water may be allowed to remain in the compress, thus rendering the reaction more slow and enduring, and abstracting more heat. In the first instance the application will be more stimulating, in the latter more soothing and antipyretic. If the patient is easily chilled or does not react readily whether the body temperature be moderate or very high, the compress may be allowed to remain longer without change; its repetition may vary from half an hour to an hour or even longer, according to the patient's condition, his reaction, and the effects produced and aimed at. Such cautious adaptation will gradually improve and regulate the reactive capacity of the patient, and sooner or later will enable him to bear more frequent repetition. It must always be borne in mind, in all application of cold water, that shock is to be avoided; there should be no prolonged chilliness, no chattering of teeth, no cyanosis of lips, nails, or face—in fine, every manifestation which indicates a depressing effect demands a modification of the procedure or its abandonment, if need be. And right here let me emphasize a much-neglected point. We do not abandon quinine in malarial fever, when it produces distressing effects. On the contrary, bearing in mind the importance of the remedy, we circumvent its untoward effects by changing the method, time of administration, etc. Cold water is often entirely abandoned when it produces unfavorable manifestations, which is a serious error. Treat it as you would any other remedial agent: change the method, the temperature, the duration, and you will be gratified by the result, for it is a most flexible agent, as I have shown.

Besides the general effect referred to, we observe a local stimulating effect upon the cutaneous circulation. The arterioles contract under the cold compress; but they quickly dilate again, as is evident from absence or disappearance of chilliness, and the gradual warming up of the part, so that when the compress is removed in an hour it is quite warm. This dilatation, be it remembered, however, is not a passive one like that under a warm poultice. The skin does not wrinkle and become cyanotic, but remains smooth and becomes ruddy. Moreover, each repetition again stimulates the walls of the arterioles to contraction and dilatation, propelling the blood-flow through them, and thus relieving the overburdened heart of much labor. Romberg and Paessler have recently confirmed by laboratory experiments what I have several years ago and repeatedly since that time insisted upon, that in acute infectious diseases we encounter disturbances of the circulation which manifest themselves clinically as reduced tension and diminished filling of arteries, and which are commonly described as heart failure. Undoubtedly this condition of the peripheral vessels bears a very large share in the production of cardiac inadequacy, as I have sought to impress when explaining the rationale of cold applications in typhoid fever. Romberg has shown by experiments with injections of Fraenkel's diplococci into rabbits that the circulation is damaged by a paralysis of the vasomotors while the heart itself remains unaffected. By restoring the lost resiliency of the cutaneous arterioles, the compresses referred to relieve the heart of much labor—labor, too, which it vainly endeavors to compensate by increased contractions, the sum of which too often leads to heart failure.

Upon this principle we endeavor to meet the second indication in pneumonia.

The third therapeutic indication, the elimination of noxious products, is signally met by the improved conditions of the central nervous system and of the heart, these presiding over all the functions of the body. The urine shows by its increase in quantity and toxicity that the most important noxæ are eliminated with great activity under the external application of cold. In addition to the latter the systematic administration of ice-water (45° F.) ℥ iv. every two hours, acts as a cold douche to the stomach and by increasing arterial tension increases urinary excretion. Allow me here to controvert an erroneous idea which is almost universal, viz., that it is the increased quantity of water imbibed which increases the urine (I have observed an increase of one to four hundred per cent.). Glax has shown, and I have confirmed his finding, that the imbibition of very hot or very cold water acts upon the arterial tension, and consequently upon urinary excretion, precisely as in its external application, and not by reason of the quantity drunk. This is readily demonstrated by the fact that only a slight increase of urine is produced by drinking tepid water, and the quantity is increased with the thermal difference between the body temperature and that of the water drunk. It is my custom, therefore, to alternate oz. vi. milk or other liquid food with oz. iv.–vi. of very cold water (45° F.), giving each every hour, in pneumonia. The result is systematic nutrition and renal stimulation.

The fourth therapeutic indication is certainly fulfilled by these mild applications of cold in pneumonia. The comfort of the patient is greatly enhanced by the reduction of temperature, deepening of the inspiration, and general *bien-aise* which are renewed on each application. The cold compress, when its temperature is equalized to that of the patient's body, really becomes a poultice, soothing, relieving pain, dyspnœa, shallow and rapid breathing, but not relaxing the cutaneous vessels and elevating temperature, as does the old-fashioned hot poultice. Another important result of the cold compress has been demonstrated by Winternitz and others—an increase of the blood cells beneath it when reaction occurs. How much such an awakening of leucocytosis and such a removal of the blood cells from dormancy into the general circulation must contribute to enhance the natural processes of restitution, is self-evident.

To sum up briefly the effect of judicious hydrotherapy in pneumonia, I would say that while it is not a direct curative agent, it fulfils all therapeutic indications, efficiently forestalling or controlling all the depreciating elements of the disease. Only one condition is unaffected by this treatment, viz., resolution. I have observed crisis in only about twenty-five per cent. of cases. The local course of the disease appears to be changed. Resolution proceeds more slowly but more surely. The patient has a normal temperature and pulse, and almost normal respiration from five to twenty days before all signs of consolidation have disappeared. In the mean time I permit him to go out in mild weather, and endeavor to hasten convalescence by the usual measures, good food, gentle outdoor exercise, ventilation, etc. I am still unable to explain theoretically this retardation of resolution in fifty per cent. of the cases, except on the same principle as the relapses in typhoid fever after the Brand treatment may be explained, viz., there are more cases escaping death, and therefore, more to relapse. The cases which do not have crisis and resolution would probably be added to the great silent majority, or pursue a slow course toward convalescence, if not treated hydrotherapeutically.

THE USE OF HYPNOTISM IN GENERAL PRACTICE.[1]

By E. H. MARTIN, M.D.,

CLARKSDALE, MISS.,

COUNTY HEALTH OFFICER OF COAHOMA COUNTY, MISS.; FORMERLY PRESIDENT OF THE TRI-STATE MEDICAL ASSOCIATION OF MISSISSIPPI, ARKANSAS, AND TENNESSEE.

It is not the purpose of this paper to deal exhaustively with the subject of "hypnotism." It is to be taken for granted that, in this enlightened age, every practitioner of medicine has a general knowledge of the usefulness of suggestion as a therapeutic agent The literature of the subject is voluminous. I have nothing new to add to the mass of data available to every one. My only excuse for this paper, then, is the tendency of most members of our profession to shirk their duty to use this agent in proper cases in general practice, and to relegate its use to specialists and quacks.

The idea seems prevalent, not only among the laity but in our own ranks, that hypnotism can be of use only in cases of hysteria and nervous affections. The truth is exactly to the contrary, as I will show further on. Hypnotism is of relatively little use in hysteria, though minor forms of suggestion are useful in that real malady. Hypnotism, in its many forms, has been used as an adjunct to the healing-art from the earliest days. If we are to believe the Garden-of-Eden story, the first use of anæsthesia on record was by means of hypnotism, when the Lord caused a deep sleep to fall upon Adam, and exsected a rib; and the product of that rib has had a tendency to hypnotize us ever since.

Lack of knowledge of the true *modus operandi* of suggestion kept hypnotism in disrepute for thousands of years and confined its use to priests and so-called sorcerers and wizards, later to charlatans and mountebanks. But the truth in it could not be kept down by all the cloaks of pretence and formality. Not even Mesmer's extravagant theories of animal magnetism could kill it. Rescued by Braid and elucidated by the school of Nancy, it now rests upon a sound scientific basis, and no one need, as formerly, be ashamed to practise it. In fact, it is our plain duty to use it in some cases.

The modern theory of suggestion and hypnotism depends upon the recognition of the fact that the conscious mind is the product of the activity of the cells of only a part of the brain. Other parts of the brain are ordinarily not under control of the mental efforts. We must know, axiomatically, that every organ, every blood-vessel, every capillary, every square millimetre of skin and tissue is connected with the brain by nerves, and that the nutrition of every part of the human system and the function of every organ are under the control of some centre in the brain. These centres do not act blindly and automatically always. There must be some grand controlling centre or portion of brain tissue that governs the entire system of centres.

The product of the activity of this part of the brain we call the "sub-conscious mind," in contradistinction to the conscious mind. Ordinarily we find but little connection between the "conscious" and the "sub-conscious," to use the shortened expression. But there is some connection, and many everyday incidents show it. For instance, a man cannot, by taking thought thereof, increase or decrease the rapidity of the pulse. But some sudden shock, danger, fear, joy, or pain can affect the "conscious" deeply enough to impress the "sub-conscious," and a change of pulse rate ensues. The blush is another illustration.

[1] Read before the Mississippi State Medical Association, at Meridian, Miss., May 16, 1900.

Very few of us can blush at will or can refrain from blushing by wish, but an impression of the proper, or improper, kind will cause a dilatation of the capillaries of the cheeks of those not too hardened to receive a shock, an impression on the "sub-conscious" through the "conscious" mind. The familiar fact that some people can, on retiring, think hard enough of waking at a certain time to impress the "sub-conscious," which at the appointed time nudges the "conscious" awake, is another illustration. Mental excitements of various sorts have various effects through the "sub-conscious" upon even the larger organs. The heart has already been mentioned.

An unusually large increase in the secretion of urine is often observed after mental excitement. The sensation of nausea often comes through mental effect only, even to causing the husband, at too rare times, to feel the nausea of pregnancy; a great fright will sometimes cause imperative and immediate defecation, and "cold feet" are not unknown, even in the army.

Thus we see that the function and nutrition of every part of the system, even of the thinking part of the brain itself, is controlled by the vague "sub-conscious," which never sleeps. We also see that under ordinary conditions the "conscious" can affect the "sub-conscious" but little, while under extraordinary but everyday conditions the effect is vastly greater.

Now we have to find only a means whereby we can make impressions at will upon the "sub-conscious," and we can then do wonders toward controlling the functions otherwise beyond control. This we find to a greater or less extent in suggestion or hypnotism. I use the word "suggestion" as meaning an impression made upon the "sub-conscious" through the "conscious" mind, either during sleep or in the waking state, and the word "hypnotism" to mean impression or suggestions made during sleep only and when this is artificially induced. There is really no difference between hypnosis and natural sleep, except that in the latter the subject is in connection with no one but himself, while in the former he goes to sleep with the memory of the operator most prominent, and is, therefore, more or less under the operator's control.

During natural sleep and during hypnotic or induced sleep, and also during the lighter stages of hypnosis, when we have only drowsiness and no loss of consciousness, the conscious mind is in abeyance, takes a back seat, and the "sub-conscious" mind, controlling every function of every part or organ, comes more or less to the surface, and is more or less susceptible to impressions from without. For instance, a man awake is given a dose of inert substance which he is made to believe is an emetic; his conscious mind dwells so strongly on the idea of emesis that an impression is soon made upon the "sub-conscious," and emesis follows. That is simply suggestion, because the relation between the "conscious" and the "sub-conscious" is undisturbed. But if, by means of any of the methods in vogue, a drowsiness or a light sleep or a deep sleep is induced, and the inert substance administered with the suggestion of emesis, or the suggestion is made alone, emesis more certainly follows. That is hypnotism, because here the normal relation between "conscious" and "sub-conscious" has been disturbed.

A patient, during hypnosis, is given a swallow of milk and assured that it is castor oil; the impression is made almost directly on the "sub-conscious," and the effect of castor oil promptly follows. Another experiment showing the complete control of the vaso-motor system by the "sub-conscious" is that of the mental blister. It has succeeded many times, but requires a very fine subject, *i.e.*, one in whom the "conscious" can be made to give way to the "sub-conscious" entirely. A piece of paper or a few postage stamps are applied to the patient's skin; the patient is assured that the application will blister, a bandage is applied, and the patient is watched. If the suggestion has "taken" with the "sub-conscious" the blister follows. And why not? It is really not so wonderful; the brain centre that can bring the blood to the surface in a blush can surely keep it there if duly controlled.

As I have before stated, the "sub-conscious" controls not only the functions of every other organ, but of the thinking part of the brain itself. By suggestion, the thinking part of the brain can be made to think more or less with the operator; the hearing part of the brain to shut out sounds that are and to hear sounds that are not; the seeing part of the brain to be blind to that which is before the eyes and to see things that do no exist; the feeling centres to refuse to receive messages from without or to feel pains that are not real. And this "sub-conscious" also has a memory apart from the everyday memory.

If you are made very sick from eating or drinking a certain article, the "sub-conscious" rarely forgets it. Years afterward a single taste of that article will induce nausea. So if an order be given to a patient during hypnosis, an order that is to be obeyed days afterward, the patient may or may not have any conscious memory of the order, but the "sub-conscious" will remember it, and the order will be obeyed with more or less exactness, depending upon how perfectly the impression was accepted. This is called "post-hypnotic suggestion."

And now we come to the application of the facts which I have tried to make clear. What class of cases call for suggestion? We may rightly divide all cases into three classes in this regard: (1) Those cases which nothing will do so well as hypnotism; (2) those cases in which hypnotism will be of great assistance to other treatment; (3) those cases in which hypnotism is not worth while. Under the first head come many morbid conditions that ordinarily baffle the doctor. Persistent insomnia is one. It is very doubtful if we are justified in using drugs to produce sleep night after night if we can gain the same result by hypnotic suggestion. That we can do so in most cases is a fact. That to use drugs in such cases makes us responsible for many instances of drug habit is also a fact.

I will give one case to illustrate the use of suggestion in this trouble. The patient, a lady of more than ordinary intelligence, had not only been ill for some time but had been under severe mental strain, and her physician has been compelled to use drugs to induce sleep for several nights. I was called, and the use of hypnotism was consented to. She was readily influenced, and light sleep was induced. She was ordered to go to sleep every night at ten o'clock and not to awaken until six in the morning. When awakened from the hypnosis, after five minutes she remembered the order and laughed rather incredulously; she said she hoped it was possible, but that as chloral in ordinary doses had failed for several nights she was afraid it would not work. That night her nurse was agreeably surprised to see her turn over and drop off to sleep as the clock struck ten, and she slept until 6 A.M. This went on for several nights, until some unusual disturbance caused her to wake up suddenly one morning about one o'clock, and the impression lost its effect. The next day I repeated the hypnotic suggestion, and she had no return of insomnia.

Another trouble in which drugs are sometimes failures is the nausea of pregnancy. Here it is impossible to remove the cause without interfering with the sex function of the woman. What more rational than to cut off the disturbing messages from the sexual organs before they reach the vomiting-centre in the

brain? Five minutes of hypnosis, a few positive suggestions, and you can awaken your patient feeling reasonably sure that if you have made an impression on the "sub-conscious," that all-powerful secretary of the interior has shut the vomiting-centre off—has disconnected it at central, so to speak.

Another condition in which drugs are not only useless but worse than useless, is in cases of pressure pains of pregnancy. About the fifth or sixth month of gestation it sometimes happens that the enlarged uterus presses too much upon one or both sets of nerves passing over the brim of the pelvis. The result is intense pain in the hip or thigh. This pain is often so great as to interfere with the daily life of the patient. She is most probably a multipara, and has a lot of little children to care for, and so she cannot stay on her back all the time. Life under such circumstances becomes unbearable; but what can the doctor do? He cannot remove the cause—the pressure on those nerve trunks. The condition is not grave enough to call for the destruction of the unborn child; morphine is his only weapon, and its use for weeks means the habit. But if he will hypnotize the woman, and, by suggestion, prevent the brain from receiving those messages of pain, he will have solved the problem. A case is given below to illustrate:

Mrs. B——, aged twenty-three years, pregnant five and one-half months with her fourth child, had been in bed a week. Any attempt even to sit up was followed by excruciating pain in the right hip and thigh. She had been using a douche in the knee-chest position by my order, but the pressure was only temporarily relieved each time. I hypnotized her and ordered that the pain should stop, that she should not feel it again in any position. I woke the patient in three minutes. She had no recollection of any order I had given her, but the pain was no longer felt. The next day I found her up, sewing on baby clothes. A week later the pain returned, and the suggestion was repeated with success. In this case hypnotic suggestion had to be used several times, but the patient passed through gestation comfortably and without morphine.

Another condition which will try a doctor's soul is that of "wrenched back." The physical injury is so slight in proportion to the pain caused that one can only sit and wonder. It may not amount to a sprain; no ruptured ligament is present; it is just a "stitch in the back," as the darkies say. It may have come from a sudden turn in lifting even a small weight, it may have come from merely pulling on a boot. But there is your patient, rolling his head because he can't roll anything else, and groaning at the slightest movement of his body. I say "his" because I have never seen a case in the female sex. There he is, and there he is apt to stay for from three days to a month, and what are you going to do about it? Local applications seem to do no good, morphine gives only partial relief, and every day you go to see that man you wish he would get sick or had broken his leg. In the mean time he is eating three square meals a day, and losing his confidence in all doctors in general, and in you in particular.

Here is a case in question, Mr. McE——, aged about thirty-five years, by occupation a railroad section foreman. In helping to lift a railroad tie his foot had slipped on the side of the dump, and he had fallen. He had not fallen hard, but he said that his body gave a turn, a pain struck him in the back, and he collapsed. It took the entire section crew to take him off his car and put him into bed, and several more to get his clothes off. Four men risked his profanity in order to turn him over so that I could examine his spinal column. I could locate no injury. I prescribed a liniment and gave him morphine. The next day, there being no improvement, I put hot applications on his back and gave more morphine. The next day it was ice to the spine and morphine. The next day I found that he was using hot ashes externally and morphine internally. At the end of the week the skin on his back was about used up, as was all of the horse liniment, coal oil, turpentine, etc., in the local store, with which he had been helping me treat the case. It then occurred to me for the first time to try hypnotism. His condition was no better than when I first saw him, and I was ready to try anything. He went to sleep almost at once. In fact he was one of the best subjects I have ever seen. I made appropriate suggestions, and finally ordered that he would sleep one hour and then wake up free from pain. In one hour he did wake up, got up and dressed, and went out to work. He did not have another moment's trouble with his back.

That same patient sent for me one night at a later date to extract an aching tooth. I found him suffering all that toothache means, and proceeded to hypnotize him, as at that period I was so enthusiastic about hypnotism that I never did a minor surgical operation without trying to get hypnotic anæsthesia. Having put him to sleep, I examined the tooth and found the cavity very small and the tooth very much needed; so instead of extracting the tooth I ordered him to quit having the toothache. I assured him that it would never ache again, etc. I then waked him up and explained to him what I had done. He was gratified at saving the tooth, but very unbelieving as to the loss of the toothache. In fact he would not let me leave him until he had tried ice-water and molasses and everything else at hand to try to make the tooth ache again. Three years later he told me that it had never ached afterward.

The conditions in which hypnotism is better than drugs can be multiplied. I have given only a few instances, but the cases under class No. 2, in which hypnotism may be of great assistance to other treatment, are even more numerous, while the cases under class No. 3, in which hypnotism is not worth while, are by far the most numerous of all.

Before leaving class No. 1, I will mention headache not of organic origin; even in the latter relief can be given, but in cases of nervous or functional headache hypnotism is really a cure, frequently a permanent one.

Under class No. 2, we have a vast number of conditions in which hypnotism is a very useful adjuvant to treatment. Not to go into tiresome detail, I will simply report a few cases of my own employment of it, and the thoughtful can readily see when it can be brought into use advantageously, merely to remove a troublesome symptom.

A negro woman with tertiary syphilis could not retain even a small dose of iodide, and the drug was very badly needed. I hypnotized her, and ordered her to retain the medicine. She did and recovered rapidly.

A young girl was in the tenth day of lobar pneumonia; resolution was well under way; there was no fever, but the patient was in a state bordering on collapse, could retain neither nourishment nor drugs. She was plainly slated for a speedy death under ordinary circumstances. I hypnotized her, ordered her to sleep two hours, to wake up hungry, and to retain whatever was given her. She obeyed orders, and not only retained all that was given her but called for more, developed a ravenous appetite, and recovered rapidly.

In this and a few other similar cases I am confident that I have actually saved life by making nourishment and stimulation possible. In one case of persistent vomiting in lysæmia, or malarial hæmaturia so called, the vomiting was controlled and the medicine retained.

When chloroform is objected to during labor, hypnotism can often be used, though few women now object to chloroform when the labor pains become severe. I delivered one woman of a large boy after keeping her in hypnotic sleep for ten hours. The case was very difficult and podalic version had to be performed. During the operation of turning the pains were entirely suspended by means of suggestion. At all times the pains were under my control and could be increased or diminished in severity or frequency by suggestion. That sounds hard to believe, but it is a fact. It was the first time the woman had ever been hypnotized.

In minor surgical operations anæsthesia can often be induced and an abscess evacuated, a tooth extracted or filled, or a few stitches taken painlessly. I have amputated a thumb during complete anæsthetic hypnosis.

But here are to be met many disappointments. Nearly every patient can be hypnotized to some degree; even if only drowsiness is obtained, the post-hypnotic suggestions are generally, at least, partially effective. But complete surgical anæsthesia can rarely be induced; very often the pain is partly relieved, but only in a small proportion of cases is it completely so. This is probably because a post-hypnotic suggestion has a longer time in which to sink into the "sub-conscious," while the immediate suggestion of anæsthesia is hardly accepted and grasped by the "sub-conscious" before the operation begins. Also the patient goes to sleep expecting pain, and that expectation acts as a counter-suggestion. Repeated hypnoses, with suggestion as to future hypnosis with anæsthesia, might be effective, but that is rarely practicable.

And now having, I hope, shown that hypnotism is a useful therapeutic agent, and that it is every medical man's duty to understand and be able to use it in general practice, let me add a word of caution. Do not use it too often. Never use it unless you think the case demands it. Never under any circumstances use it for fun. I would as soon think of giving a man ether to amuse a crowd as to hypnotize him for the gaze of the curious. In the first place it is not right, and in the second place it does not pay. It brings this useful agent into disrepute, and as you will fail more often in parlor play than in practice, it will bring you as a successful operator into disrepute.

I have said nothing as to methods, because there are so many methods, and you will find them all in the text-books. Read Moll first, then Bernheim, and then you will probably be well enough placed on the subject to read more extravagant authors without believing all they say.

I have not referred to the use of hypnotism in treating naughty children for their bad habits, or its use in any other special way, as those things are beyond the scope of my paper.

A word before closing as to the use of hypnotism in cases of hysteria. Here we will find ideal cases and surprising disappointments. In a few cases it may be found useful, but in most cases you will fail to hypnotize the subject. Hysterical patients resist hypnosis most when thinking that they are trying the hardest to go to sleep. If you do succeed in influencing them they will go into astonishingly exaggerated stages of hypnosis, catalepsy, somnambulism, will exhibit contractures, etc. You feel sure that your suggestions will be effective, but if they are and one hysterical symptom is removed, another may soon take its place. The reason is obvious. Hysteria, this disease without a lesion, is evidently a functional derangement of the "sub-conscious," and with the "sub-conscious" deranged we cannot hope to use it to follow our suggestions. It is with the "sub-conscious" that we accomplish everything in the domain of hypnotism. The "sub-conscious" is our servant, and to be useful it must be in good working order. I do not know that this definition of hysteria has ever before been given, but I am sure that psychologists will agree with me that hysteria is not a derangement of the conscious mind, but of the functional activity of that part of the brain the product of which has been called the "sub-conscious" mind.

Simple suggestion does more good in the largest number of cases of hysteria than hypnotism. There already exists a disturbed relation between the "conscious" and the "sub-conscious"—not the exact disturbance that we seek in inducing hypnosis, but sufficient and of a nature to permit suggestions to be readily accepted if agreeable to the patient.

So we see scores of these people benefited by religion and especially by osteopathy, Christian science, faith healing, or anything else that gives prolonged suggestion of cure. These are all fraudulent systems grounded upon false premises. We still may use them in rare selected cases, preferably through the advice of a third person; we can hardly face a patient and prescribe Christian science, so called. Still, if we know the patient to be just that sort of a hysteric that needs prolonged suggestion, have we the right to advise against it?

SOME POINTS BEARING ON THE MEDICINAL TREATMENT OF APPENDICITIS.[1]

By CHARLES ROSEWATER, M.D.,
OMAHA, NEB.

Deluded on the one hand by some over-zealous surgeons who see things only from their own point of view, and awed on the other by the fear of fatal results from surgical procedures, the general practitioner stands, as it were, between Scylla and Charybdis, not knowing which way to turn or what course of action to pursue. The one class of practitioners tells him that he is not doing his duty by his patients if in a case of appendicitis he does not promptly call in a surgeon and have the offending appendix removed. On the other hand, he may have seen and certainly may have heard and read of instances when a simple, uncomplicated, non-septic appendicitis, or no appendicitis at all, was found upon abdominal section, and in which the patient died from the operation which was found to have been entirely unnecessary.

Again, we see cases in which a timely recourse to surgical measures might have saved a patient who was allowed to die either for want of the proper diagnosis or proper interpretation of the indications present.

We are brought face to face with these grave conditions often enough to feel the weight of responsibility resting upon us. We wish to do our full duty by our patients. Which way shall we turn? What course shall we pursue so as to insure the greatest safety to the patient?

Still another class of cases presents itself in which every indication warrants and demands surgical intervention, but the patient's general condition, or the serious impairment of some vital organ, would hold out little hope for the success of such a procedure. The patient could not stand a laparotomy. What shall we do? Shall we sit down, fold our arms, and say, "Nothing can be done"? Most assuredly not. Yet this is just what I found several members of our profession, otherwise excellent men, do, simply on account of a misinterpretation of their duties to their patients, or on account of blind faith in the guidance of some over-zealous surgeon who has issued the dictum, "Operate in all cases if you wish to do your full duty."

[1] Read before the Nebraska State Medical Society at Omaha, May 10, 1900.

This is the dilemma in which the medical profession to-day finds itself. Before seeking the path which is to lead us out of this labyrinth of doubt and uncertainty, a little review of the conditions which confront us will not be amiss.

Appendicitis, an inflammation of that little offshoot from the bowel in the ileo-cæcal region, whose function no one has so far been able to determine, may be catarrhal, suppurative, septic, or perforating; it may be simple, or, what is more frequently the case, complicated by a localized peritonitis, involving the peritoneum of the ileo-cæcal region, or spreading over the entire abdominal peritoneum. This peritonitis is, of course, accompanied by the formation of a plastic exudate, which agglutinates the various coils of the bowels and, becoming organized, permanently impedes their vermicular movements, thereby impairing intestinal digestion. Intestinal movement becomes imperfect, painful, and deficient, and the contents of the bowels are not evacuated as they should be. Fecal accumulations are liable to occur, causing new irritation and leading to inflammatory attacks, the relapses to which the subjects of appendicitis are so liable.

The primary attack of appendicitis sets in sometimes without any marked symptoms of invasion, insidiously producing its pathological changes without the patient's being aware of any local pathological process until the introduction of some irritating ingesta, the use of a cathartic, a sudden exertion or a direct injury, produces decided local and general symptoms, pain referable to the right groin or sometimes to the umbilicus, vomiting, and, as a rule, constipation. Now the physician is called in, and finds a tense, tender abdomen, the tenderness being greatest at the spot known as McBurney's point; the abdominal muscles are rigid; the pain is constant, temperature elevated, tongue badly coated, pulse rapid and small. Close questioning will elicit the fact that the patient has not been well for some time past, suffering from anorexia, occasional colicky pains in the abdomen, especially in the right groin, and constipation; but he was either too busy to attend to it, or did not think it of sufficient importance to require any special attention.

In other instances a sudden, sharp abdominal pain, accompanied by all the symptoms of shock and septic peritonitis, announces to the physician that some septic accumulation has ruptured into the general peritoneal cavity. The locality and previous history tell the rest of the tale, and, if they don't, the findings of a laparotomy or post-mortem examination will reveal them. Let us see what has been the local condition which has gradually brought about such results.

That only a very small percentage of cases of appendicitis are really primarily due to the lodgments of a foreign body in the cavity of the appendix is now generally conceded, but the majority of cases are due to colds and improper diet. The first step in the pathological process is the congestive swelling of the mucous lining of the appendix with narrowing and final closure of the opening into the bowel; then a retention of the accumulated secretions in the cavity of the appendix, distention of the latter, thinning and softening of its walls, with sometimes local ulceration from the mucous surface and in other cases gangrene of portions of the wall, and rupture. Meantime, however, the inflammatory action has not been confined to the mucous and muscular layers of the appendix, but, attacking its peritoneal covering, produces a peritonitis which most frequently is circumscribed, creating a localized tumefaction in the right iliac region containing either a plastic effusion or pus, and walled off from the general peritoneal cavity by the surrounding adhesions. The presence of this tumor in the groin, the course of the temperature, and previous history of the case will assist the physician in recognizing the presence of pus, and consequently the urgent need of surgical intervention.

The treatment of appendicitis must, of course, be carried out along the lines indicated by the conditions found and impending dangers to be avoided. As the presence of intestinal accumulations threatens to aggravate the inflammatory conditions by local irritation, the first step in such a case should consist in the thorough emptying of the bowel by a mild mercurial purge (calomel) followed by a saline cathartic. A copious enema of warm salt water, a gallon or two, injected high up into the colon, assists materially in many cases, but should not be resorted to when, by increase of the peristalsis, the rupture of an abscess may be brought about. Ice applications locally, in the form of an ice-bag over the groin, do much to assuage the pain; in fact, I have found them so beneficial that the patients, after becoming accustomed to the ice, will not do without it. Opiates should be avoided as much as possible, not because they stop the peristalsis, but because they so mask the picture of the disease as to leave the physician at sea as to its progress. The patient should remain in bed on his back, with his surroundings quiet. His diet should be confined to liquid food, preferably peptonized milk, either warm or cold, according to his predilection. All solid food and such as leaves much waste should be forbidden until all signs of local irritation have subsided. Too great care cannot be taken in this particular during the first year following an acute attack of appendicitis, for upon this care will depend the permanence of the recovery. In the beginning of an attack, when vomiting is a prominent symptom and the stomach is very irritable, gr. $\frac{1}{20}$ of calomel given hourly will quiet this irritability in a large proportion of cases. Bits of ice swallowed at intervals will assist in accomplishing this result. Sometimes iced champagne is retained in small quantities by such a stomach when other fluids are vomited. To combat the fever and nervous manifestations, salol and phenacetin, gr. ii. of each every two to four hours, with gr. $\frac{1}{4}$ of citrate of caffeine, yield good results. Judicious stimulation during the use of phenacetin is deemed advisable. The treatment outlined here is carried on during the height of the disease, with the object of relieving the local irritation and checking the progress of the inflammation until resolution sets in. As the inflammation subsides, gradually a new element enters into the treatment, namely, the removal of the effects of this inflammation, the removal and absorption of the inflammatory exudate, which, if allowed to remain, leads to agglutination of the intestinal coils and permanent impairment of the intestinal activity. To attain this object I have used with good success iodide of ammonium in doses of gr. i.–iii. every four hours, followed by copious draughts of hot water. In fact, all through the attack of appendicitis hot water should be given freely and in large quantities. My experience with this treatment has been very gratifying in cases of appendicitis in which patients, apparently needing surgical intervention, have refused to be operated upon. It was employed with satisfaction in one case in particular, in which serious valvular heart trouble led me to fear an operation, and in which the treatment was instituted without expectation of favorable results, eight months after a second attack of appendicitis. The patient, aged twelve years, presented a history of arsenical poisoning occurring at the age of two years, followed by an irritable digestive canal, and chorea; at the age of eleven years she had her first attack of appendicitis, followed in a few months by a relapse. Eight months had passed by since the partial recovery from the relapse, and a number of physicians who had been consulted declined to treat her, claiming that nothing could be done without an operation. In view

of the peculiar complications in the case rendering an operation extra-hazardous, I felt justified in postponing serious consideration of the latter and instituting the treatment as outlined above. The result was immediate improvement and ultimate complete recovery from the effects of the appendicular trouble. This patient suffered from chronic constipation due to the agglutination of the intestinal coils, but was entirely relieved after the treatment with iodide of ammonium and copious hot-water draughts was instituted, so that her bowels acted regularly without a laxative. This proved to me conclusively that the adhesions must have been removed and the intestinal peristalsis re-established.

It is to this phase of the subject that I wish to call especial attention, applicable as it is in numerous instances in which operative procedures are not feasible and are always dangerous. I do not wish to be understood as opposing surgical measures, especially when they are clearly indicated and not contraindicated by the presence of other dangers.

On the Symptoms or Phenomena Formerly Known as Croup; the Diseases which Produce Them; and the Clinical Significance of the Various Allied Affections Embraced by the Term.—The conclusions of Langford Symes are as follows: (1) There is no such true disease as croup, croupy symptoms being produced by a variety of different diseases. (2) Severe croupy symptoms are most likely to be due to either diphtheria or laryngitis stridulosa. (3) In a difficult case we should suspect diphtheria and treat it as such from the start with antitoxin. (4) Recession and restlessness are the two most dangerous symptoms. (5) As antitoxin reduces the mortality of diphtheria and enables cases to be tided over the crisis with intubation, it may possibly contribute to the future success of tracheotomy. (6) Deaths registered as croup are mainly due to diphtheria.—*Dublin Medical Journal*, July, 1900.

Treatment of Diarrhœa in Tuberculous Subjects by Abdominal Faradization.—E. Doumer has had good results from this therapeutic application of the faradic current. The electrodes are covered with chamois skin and are applied well moistened over the entire surface of the abdomen. The *séances* should last five minutes and should be repeated two or three times daily. The tampon electrodes should be particularly applied along the course of the colon, and the current should be strong enough to produce good contractions of the abdominal muscles. The first improvement noticed is in the diminution of the number of stools; later their consistency changes and they become formed. By the fourth or fifth day the cure is generally complete.—*Le Nord Médical*, July 1, 1900.

The Significance of a Temporary Temperature Rise Limited to the Day of Hospital Admission.—Fromm has studied the case histories of over two thousand patients and found that of this number one hundred showed a rise of temperature on the first day, which speedily subsided again, and in most instances without any medication. In analyzing these cases it was found that in nearly fifty per cent. some disease of the respiratory system was present, and one-half of these were tuberculous. The fact has been established by Penzoldt and Höchstetter, that in tuberculous individuals moderate exercise causes a much greater temperature elevation than is produced under similar conditions in the healthy. Adopting the view that the increased circulatory activity causes the distribution of a larger amount of toxin from a tuberculous focus, it seems rational to explain this anomalous "first-day rise" on the ground of the unusual exertion and bodily and mental disturbance involved in reaching the hospital. In other cases, no doubt the change to the quiet and proper nursing of the hospital causes the subsidence of a moderate fever already present. In concluding, the author states that, other things being equal, the existence of this first-day fever may serve as an additional factor to strengthen a presumptive diagnosis of tuberculosis.—*Centralblatt für Innere Medicin*, June 30, 1900.

Latent Tuberculosis of the Pharyngeal Tonsil.—L. Réthi reviews the recent voluminous literature on this subject, adding the results of his own observations. Among one hundred cases examined, tuberculosis was found six times, cheesy degeneration being present in two of the six cases. In five the tuberculous deposit was near the surface under the epithelium and once in the deeper layers. Giant cells were present in all six.—*Wiener klinische Rundschau*, No. 26, July 1, 1900.

Congenital Elephantiasis.—J. E. Dubé gives with illustration an account of a child two and a half months old, whose right leg was enlarged at birth and continued to increase in size until the foot was almost hidden from view, and the calf and thigh presented enormous proportions. The mother had had a fright in the third month of her pregnancy. The leg was treated by deep multiple puncture and elastic compression. At each sitting a large amount of orange yellow thick serum ran out and coagulated at once. There was some improvement up to the time the patient disappeared from observation.—*L'Union Médicale du Canada*, June, 1900.

Two Rebellious Cases of Pyorrhœa Alveolaris Cured by the Cruet Method.—J. Chaminade says text books as a rule recommend only chromic acid. Two observations are given in which the application of the thermo-cautery, after mouth washes containing thymol and menthol and careful cleansing of the dental arcade had prepared the way, resulted in perfect and permanent cure. The point of the cautery is passed from the margin of the gum to the deepest points opposite the root of the tooth, and is made to enter all cul-de-sacs so as to destroy all infectious foci. Antiseptic washes follow the application.—*Annales de la Policlinique*, June, 1900.

Two Cases of Malarial Hæmaturia with Treatment.—A. E. Cox treated a man aged twenty-one with calomel in five-grain doses every two hours until twenty grains were taken, strychnine sulphate every four hours (one-thirtieth grain), cold to the head, with tepid sponging first; and if this did not reduce the fever his patient was to be sponged with cold water. The patient had taken quinine, and this was continued in five-grain doses every three hours until six doses were taken. The patient continued to pass bloody urine, so the quinine was discontinued and sodium hyposulphite in drachm doses every four hours was ordered, to be diminished after the bowels should move freely. Strychnine was continued and one dose of morphine with atropine given hypodermically. Under this latter treatment the patient rapidly convalesced. A second case was treated in practically the same way with equally good results, except that no quinine whatever was given.—*Memphis Medical Monthly*, July, 1900.

Remarks upon the Diplococci Resembling Gonococci Found in the Normal Vagina of Children.—C. A. Rosenwasser calls attention to the need of further study of a condition of great importance, viz., the vaginal discharges of childhood supposed to be caused by gonococci. Instances are reported of outbreaks

in children's wards despite all precautions. The work already done in the study of intracellular diplococci resembling gonococci, decolorizing or not by the Gram method, is reviewed. The author has demonstrated in the apparently healthy vagina intracellular diplococci, decolorizing by Gram, differing from gonococci only in not having the typical arrangement. He thinks it may be that some vaginal discharges are caused by an attenuated or not fully developed gonococcus which does not react to Gram. The reason the vagina more than the conjunctiva suffers is that the latter is not so susceptible to infection. The investigations will be continued.—*Archives of Pediatrics*, July, 1900.

The Pericarditis of Bright's Disease.—P. Chatin reviews the literature of this affection and gives histories of three personal cases. A careful examination was made of the bacterial contents of the pericardial sac in his cases, and in all there was noted a markedly weak infective power. From this, the author infers the existence in certain cases of Bright's disease of an aseptic, germless pericarditis. In other cases it is one of the complications of an ordinary infection. The suggestion is made that the disease may at times be a toxic pericarditis, but the author is not willing to express a conclusive opinion on this point.—*Revue de Médecine*, June 10, 1900.

Two Forms of Pseudo-Meningitis due to Lumbricoides.—Dr. Mériel gives the history of a child ten years of age, who, after a purulent discharge from the ear, fell sick with all the symptoms of meningitis, which was at first attributed to extension of inflammation from the ear. The ordinary period of five or six days passing and the symptoms continuing unchanged caused a doubt and led to careful inspection of the stools. The result was that two lumbricoid worms were discovered, and a few days after their discharge convalescence set in. In the second case there were in a nine-year-old child immobility of the head on the pillow, rigidity of the neck, and other symptoms pointing to meningitis, with delirium, convulsions, etc. Santonin and calomel were given as in Case I., and after four ascarides were passed the child recovered.—*Annales de Médecine et de Chirurgie Infantiles*, July 1, 1900.

The Treatment of Yellow Fever in Children.—José Texeira, basing his views upon the observation of two hundred cases of yellow fever in children, comes to the following conclusions: The disease is often complicated with meningitis, which is very dangerous; the renal complications are very rare in children. In order to avoid this dangerous complication we must from the onset of the disease apply strong derivatives to the skin, especially to the lower extremities, stimulate the perspiration of the skin and evacuation of the bowels. Large doses of castor oil and copious enemata of boric acid are very efficient. Of course, according to the conditions present, symptomatic treatment at the same time is very important. In forty cases this treatment was successfully carried out.—*Clinical Record.*

Losdorfer's Bodies: A New Discovery in Syphilitic Blood.—Victor Neudörfer looks upon the recent discovery in Vienna of bodies in the blood of syphilitics, which are perhaps the specific germs of the disease, as a striking illustration of the importance of hæmatology to general medicine. The announcement of Losdorfer in April last was received with scepticism, but Paltauf had controlled the examinations, which embraced one hundred and twenty-five syphilitic patients for over a year. He found that the bodies described often appear in the blood before the exanthem is developed, while for the first four or five weeks after infection no changes can be noticed. The bodies are not found in other patients. In the portion of the field which contains no blood corpuscles long, oval bodies having about the size of large acidophile granules or so-called eosinophile leucocytes, but not so glistening, make their appearance after two or three hours. Later on they show movement and form chains. Losdorfer is not prepared to claim as yet that they are specific for the disease. They are found also in hereditary cases, and will at all events have a diagnostic significance.—*The St. Paul Medical Journal*, July, 1900.

Cold as an Etiological Factor in Diseases of the Air Passages.—J. Zahorsky says that—(1) Common "colds" are acute infectious diseases. (2) Severe exposure acts as a general predisposing cause to infection. The detrimental effect of the manifold mild exposures is very doubtful. (3) Rarely the normal or accidental bacteria in the upper air passages may excite disease. (4) Most commonly a micro-organism from some one else having a "cold" is the exciting cause. (5) Any lesion of the mucous membrane, such as chronic ulceration in the nose, or recent lesions produced by the inhalation of dust, impure air, noxious or irritating vapors, and possibly very cold air predispose to infections of the upper air passage. (6) Congregation of persons and the non-ventilation of rooms are the principal factors which produce the increased prevalence of colds during the winter seasons. —*St. Louis Courier of Medicine*, June, 1900.

Clonic Spasm of the Palatine Muscles Producing a Sound Heard at a Distance.—G. Ostino recently saw a physician, aged twenty-six years, who from the age of fourteen had been conscious of a noise in both ears like that of a watch ticking, which could be voluntarily arrested for a short time, but would immediately return. It was especially annoying at night, but disappeared whenever he had an acute coryza. Examination of the ears revealed nothing abnormal, nor was anything except an acute coryza found in the nose. The pharynx showed a spasmodic condition of the palatal muscles synchronous with the pulse and causing a sound perceptible to the observer. The man was neuropathic, but no special cause for the spasm could be found. Its disappearance during acute coryza was attributed to the fact that the swelling of the mucosa, in which the delicate palatal muscles are contained, so hindered their action that the spasm was for the time impossible.—*Archivo Italiano di Otologia*, etc., vol. x., No. 1, 1900.

An Experimental Contribution to the Knowledge of the Toxicology of Potassium Chlorate.—S. J. Meltzer contributes an article based upon the study of experiments made by others, and upon a series made by himself at the Columbia University laboratories. He presents an analysis of the existing experimental data, pointing out some of their shortcomings, and presents some new experimental facts. On introducing potassium chlorate into the peritoneal cavity of rabbits, the animals died thirty-eight hours later in convulsions, especially of the respiratory muscles. This led to a study of the effects when the substance was injected into the brain. Opisthotonos was usually the first symptom. Tonic contractions soon gave way to clonic convulsions. With strong solutions, violent tetanic convulsions were produced. The experiments show the drug to be a strong poison for the nerve cells, which are first excited, then paralyzed. On introducing it into the circulation it seems fair to assume that a certain amount reaches the brain in sufficient concentration to excite and paralyze, especially the respiratory centre.—*Therapeutic Gazette*, July 15, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

New York, August 4, 1900.

CHRONIC BRASS POISONING.

THE physician especially is never secure unless he is always prepared for the unexpected and the expected alike. Metallic poisoning in its various forms is not uncommonly observed if carefully looked for, and not a few obscure cases might be traced to such an origin. Probably the most frequent variety of this kind of poisoning is due to lead, occurring in those compelled to manipulate this metal, or exposed to the risk of its inhalation in the form of powder. It is especially common in those employed in lead works, and in painters who use lead colors, although it is also observed as a result of the use of hair-dyes and cosmetics containing lead, of snuffs and other articles wrapped in lead-foil, of water passing through and exerting a solvent action upon lead pipes. An epidemic has been recorded among those who have partaken of cakes col ored richly yellow with lead chromate by an unscrupulous baker. Other forms of metallic poisoning are less common.

Poisoning with lead, as also with mercury, arsenic, silver, copper, etc., results occasionally from excessive or prolonged administration of these metals or their compounds for therapeutic purposes. Mercurial poisoning may occur also in those engaged in the manufacture of mirrors, and arsenical poisoning has been attributed to the inhalation of vapors from wall-papers impregnated with arsenical colors. Copper poisoning is not commonly observed, although it may occur in those engaged in operations into which either the metal itself or its alloy with zinc, namely brass, enters. A good clinical description of this condition as it occurs among artisans in brass at Birmingham, England, is given by Murray (*British Medical Journal*, June 2, 1900, p. 1334). The patient is likely to be a young workman, presenting a more or less markedly anxious expression, with a thin and haggard face, a sallow complexion, and an unhealthy and wasted appearance. He complains of gradual loss of strength, with a dry and hacking cough, cold sweats, and, possibly, hæmoptysis. Pain in the chest, loss of appetite, and progressive emaciation in addition, raise a suspicion of pulmonary tuberculosis, but careful examination of the chest fails to disclose signs of disease of the lungs, except, perhaps, those of slight bronchial catarrh. The urine is normal. The nature of the disorder is not clear, and symptomatic treatment fails to yield relief. Other cases of a similar character present themselves, and finally it is learned, upon inquiry, that all occur in those who are engaged in some way in manipulating brass—such as stamping, finishing, polishing, etc. Examination will now disclose a typical green line on the teeth, probably due to deposition of copper.

One of the earliest symptoms is anæmia, and with it there are often associated palpitation of the heart and dyspnœa on exertion, digestive disturbances, anorexia, and epigastric pain after food. Tachycardia is common, while nausea, vomiting, and thirst are not infrequent. Slight indefinite pains of a neuralgic character may be complained of early with headache, a sense of weakness, malaise, and nervousness. As the disease progresses, emaciation becomes conspicuous, with loss of strength, and tremor. The knee jerks are normal or exaggerated, unless peripheral neuritis is present. Headache is almost always present, as well as pain varying in character and situation, neuralgic and myalgic, principally in the abdomen, then in the legs, the back, the chest, etc. As a rule, digestive disturbances are present, with loss of appetite and gastralgia, and occasionally nausea and vomiting. The tongue is generally coated, moist, and tremulous. The bowels are normal, loose, or confined. There may be a dry, tickling cough, sometimes with thick, tenacious sputum, and occasionally hæmoptysis. The pallor is distinctive, the complexion being sallow, dirty, and unhealthy-looking. Symptoms of laryngeal or pharyngeal catarrh are not uncommon, with aphonia, a sense of dryness or discomfort or constriction in the throat, and a metallic taste. A feeling of oppression or nervousness, sometimes intense, is common, and so are repeated attacks of faintness or sinking, in the morning or at work. Profuse sweating may be a source of annoyance, and there may be a sense of coldness, possibly confined to one part, as the knees, the legs, or the chest. The sweat stains the linen and also the hair green. Itching cutaneous eruptions appear in various parts of the body, but there may be itching without visible eruption. Pulmonary fibrosis is common, and paraplegia due to peripheral neuritis may occur. Poole (*The British Medical Journal*, June 9, 1900) refers to marked pulsation, either local or general, of the abdominal aorta as frequently associated with the advanced stages of chronic brass poisoning, and which he thinks may be due to vasomotor disturbances.

In treatment potassium iodide failed to yield anticipated results, but phosphorus, in pills of gr. $\frac{1}{300}$ three times a day, and dilute phosphoric acid in doses of ♏ xv. three times a day, yielded satisfactory results. The use of milk as a beverage was found to be of distinct advantage.

THE PATHOLOGY OF ACUTE YELLOW ATROPHY OF THE LIVER.

THE clinical course and the pathological anatomy of so-called acute yellow atrophy of the liver suggest the possibility that this disorder represents an acute parenchymatous hepatitis of infective or toxic origin. The essential lesions consist in fatty degeneration of

the liver cells, with increase in the interstitial connective tissue, but there is some difference of opinion as to which of these processes is the earlier. The disorder, which is by no means common, usually pursues a short and fatal course, but occasionally cases are observed in which the duration is more protracted, and the lesions are rather those of acute atrophic cirrhosis of the liver. Such an instance is reported by Findlay (*British Medical Journal*, June 2, 1900), who discusses the pathology of these allied affections. The patient was a girl, fifteen years old, who presented general dropsy, excepting in the face, together with ascites. She had been jaundiced seven months previously, with swelling of the feet, the latter returning and persisting. Diarrhœa had been present for one month. There was slight bleeding from the gums, and vomiting occurred on a few occasions. Death resulted from respiratory failure. On post-mortem examination the spleen was found to be enlarged, and of increased consistency. The liver was much diminished in size, firm, and on section presented a yellowish appearance; its capsule was thickened and granular in places. The pancreas was firm; the mesenteric glands were enlarged and firm; and Peyer's patches and the solitary glands of the intestine were swollen and congested. Microscopic examination disclosed slight fatty degeneration of the myocardium, fibroid change in the spleen, a catarrhal condition of the kidneys, degeneration of the cells and hyperplasia of the interstitial connective tissue of the liver. The case is considered one of yellow atrophy of the liver, but rather chronic than acute, and reasons are given in favor of the view that chronic yellow atrophy of the liver is nothing more than acute cirrhosis of the liver, differing from other varieties of cirrhosis in quantitative histogenetic changes. In cases of yellow atrophy of the liver the degeneration of the hepatic cells is more extreme than in cases of the ordinary type of cirrhosis, tending more frequently to death than to recovery of the cell. The connective-tissue formation differs little from what is found in other varieties of cirrhosis, but the regeneration of the hepatic tissue has advanced to a greater degree than in cases of ordinary cirrhosis, and has exceeded so-called hypertrophic or biliary cirrhosis in what is by some regarded as its special feature.

SOME TENDENCIES IN MEDICAL WRITING.

Those who follow the subject have no doubt noticed in the enormous contemporary output of writing upon medical subjects, the development of certain tendencies, the ultimate results of which may prove of questionable value. Modern medical education both before and after graduation, while it is undoubtedly raising the standard of requirement and of general medical knowledge in consequence, is at the same time subjecting the medical profession to a process of smoothing-out by which the least well-equipped members of it are gradually coming to assume an appearance at least of equality with those in an intellectually higher plane. The rapid development of specialism depends to some extent certainly upon concentration of teaching force and clinical material, which has been made possible by the improvements in our educational machinery and the growing lavishness of its financial lubrication. The specialist judiciously developed is a most desirable type of medical practitioner certainly for large cities, but unfortunately the development of our specialists often leaves much to be desired in the groundwork of medical education and in general cultivation, a very considerable admixture of both of which should be present.

The great increase in the number of specialists, more or less well equipped, which our present system produces has for its unavoidable and to some extent undesirable consequence a flood of writing upon various subjects in the form of books, from small up to what must be called ponderous tomes, though perhaps the term indicates too much weight. Many such works are written expressly for the purpose of reaching and instructing the advanced student and also the general practitioner, and purport to teach the latter especially how certain things should be done which are usually left to a man with a special training.

There are no doubt many medical and surgical emergencies in the presence of which it is desirable that the general practitioner should have at hand good advice in the form of a work of reference, but such good advice cannot take the place of trained fingers guided by a trained mind, without recourse to which full justice may not always be done to the patient. Books written for the general practitioner particularly are usually not complete enough on these subjects of pathology and diagnosis, and too much space is devoted to the more easily explained subject of treatment, which ought to be left, when possible, in the hands of the man of experience. This, of course, does not refer to simple conditions about which there are no important elements of doubt. The result of this is that the reader, encouraged by apparent simplicity, gets a warped and incomplete idea of conditions with which he may have to contend, attempts too much, and is unable to cope with difficulties which in the hands of an expert would have been obviated.

Another noticeable future in medical works of the present time is that writers seem beset with the fear that their works will not mention everybody who has spoken of their subject before, and that something in medicine will escape recording. There is not apparently a clear idea among writers as to what is of merely historical and bibliographical interest, and what is of present scientific value, and also as to what is the relative importance of such things. The realization of a distinction here would reduce the thickness of most medical volumes and would not interfere with their value or accuracy. The desire to write a book on a whole department of medicine with an approximation to completeness is responsible for much that is tiresome and unnecessary in modern writing, and has led to a great deal of what is called "padding." We see the best results in the works of men who have taken a narrow field and threshed it over and over, giving us a monograph in which we can find something upon every detail of the subject, supported by evidences of work and investigation which add much

to the convincing power of the argument. Some of the most recent large publications have been written on what might be called the monograph system, and in several instances the results have been very satisfactory, so that in them we have really valuable and useful works of reference. It is a mistake on the part of a writer to try to do too much, and one way of doing too much is to write a book which attempts to do justice to a whole department of medical science.

THE TREATMENT OF PULMONARY TUBERCULOSIS WITH SODIUM CINNAMATE.

The number of remedies recommended for the treatment of a given disorder is inversely a fair index of its amenability to therapeutic intervention. This is particularly true of pulmonary tuberculosis, in the treatment of which no one drug of the many proposed has as yet received general application. Among the agents that have been used for this purpose in recent years are balsam of Peru, cinnamic acid, and sodium cinnamate (also known as hetol). Landerer and others have reported successful results from the use of these remedies. Stimulated by the favorable reports Ewald (*Berliner klinische Wochenschrift*, 1900, No. 21) began the employment of sodium cinnamate, and after the treatment of twenty-five cases of pulmonary tuberculosis by this means has reached the conclusion that, while the remedy has not yielded the anticipated results, in view of the fact that, intelligently administered, it is free from danger, it is worthy of further trial. There was no case of pure laryngeal tuberculosis; eleven of the cases were free from fever throughout their entire course; ten exhibited febrile periods of considerable duration, and only four persistent fever. In no case was a cavity of any considerable size demonstrable, but in all except two tubercle bacilli were constantly present in the sputum. In the two excepted cases, however, the conditions were so positive as to leave no doubt as to the diagnosis. The period of treatment was variable. In some cases it extended over three hundred days and more; while one patient remained under observation for only eighteen days. The treatment consisted in intravenous injections of a solution of sodium cinnamate, beginning with a dose of 1 mgm. and gradually increasing at intervals of two days up to 15 mgm. In all, four hundred and sixty-one injections were given without accident. The treatment appeared, however, to predispose to the occurrence of slight hæmoptysis, and many of the patients exhibited marked fatigue and a tendency to sleep. In many cases marked relief was afforded, the pain in the side being mitigated and the expectoration taking place more readily. No influence on the tubercle bacilli in the sputum, on the temperature, or on the sweating was observed. Recovery took place in four cases, improvement in five cases, no improvement in six cases, and ten cases pursued an uninterrupted progressive course. These results, it is pointed out, differ little from those that are obtained from other methods of treatment, especially when the aid of climatic and other hygienic agencies is invoked.

News of the Week.

The Plague is reported to have reappeared at Asuncion, Paraguay.

American Surgeons Honored.—At the centenary celebration of the Royal College of Surgeons in London on July 26th, Drs. Robert F. Weir, of this city, and William W. Keen, of Philadelphia, were given diplomas of honorary fellowship in the college.

The Dead at Pao-Ting-Fu.—Dr. Cortlandt Van Rensselaer Hodge, Dr. G. Yardley Taylor, and Dr. Maud A. Mackey are three American medical missionaries who are reported to have been massacred by the Chinese at Pao-Ting-Fu. They had been sent out by the Presbyterian Board of Foreign Missions.

More Acting Assistant Surgeons Needed.—It is reported in the daily papers that one hundred additional medical officers are wanted by the surgeon-general for duty in the Philippines and China. Only graduates of reputable medical colleges, with some experience, and under forty years of age, will be accepted.

Smallpox at Dawson City.—A report has been received by the Canadian Department of the Interior at Ottawa that smallpox has broken out at Dawson City. It is said that the disease was imported from Cape Nome. Dr. Montizambert, the Dominion health officer, has been sent to the Yukon to make the necessary arrangements for quarantine and isolation. He took a supply of vaccine with him and sailed from Vancouver on August 1st.

Pennsylvania Hospital.—Dr. Robert G. Le Conte has been elected surgeon to the Pennsylvania Hospital in succession to the late Dr. John Ashhurst, Jr. A gold medal has been awarded the management of the Pennsylvania Hospital in recognition of the services it has rendered humanity during the past century.

Lewis Stephen Pilcher, M.D., LL.D.—The degree of Doctor of Laws has been conferred by the University of Michigan and Dickinson College upon Dr. Lewis Stephen Pilcher, of Brooklyn, editor of the *Annals of Surgery*.

The Elmira Reformatory.—Dr. Frank M. Robertson, physician to the Elmira Reformatory, has been appointed acting superintendent during the leave of absence of Mr. Z. R. Brockway. The latter, upon whom there was some time ago a fierce newspaper attack for alleged cruelty, but who was officially exonerated, has resigned, the resignation to take effect December 31st. Until that time he has been granted leave of absence.

The Brooklyn Homœopathic Hospital will soon become a city institution. Under an act passed by the last legislature and approved by the mayor, the city undertook to purchase the hospital and run it as a public institution. When the details came up for settlement, there were $70,000 of debts on the hospital, which the city was called upon to assume. President Guggenheimer objected to this course until he

had examined the assets. At a recent meeting he expressed his satisfaction with the arrangements, and it was agreed that the hospital should turn over its property to the city, which should assume the debts of the institution.

The Settlement of Dr. Evans' Will.—The city of Philadelphia can now, in consequence of the settlement of all litigation over the will of Dr. Evans, the American dentist who practised in Paris for nearly half a century, proceed with the founding and establishing of the Thomas W. Evans Dental Institute and Museum. The institution has been incorporated, and it will be built on property that belonged to the testator in Philadelphia. About $3,000,000 will be devoted to the structure and its equipment and endowment. Dr. Evans left an estate amounting to a little over $4,000,000, one-quarter of which goes, under the terms of the settlement, to the direct legatees, mentioned in the will for smaller sums, and the remainder to the foundation and endowment of the Dental Institute and Museum.

The American Association of Obstetricians and Gynæcologists will hold its thirteenth annual meeting in the assembly room of the Galt House, Louisville Ky., Tuesday, Wednesday, and Thursday, September 18, 19, and 20, 1900, under the presidency of Dr. Rufus Bartlett Hall, of Cincinnati, Ohio.

Major J. Van R. Hoff, who was at the head of the army medical service in Porto Rico, has been selected as chief surgeon of the China expedition, and orders relieving him of his duties in Porto Rico and directing him to report at once in Washington have been telegraphed to him. After a consultation with General Sternberg he will proceed immediately to San Francisco and take the first transport for China.

Wholesale Libel.—A criminal prosecution for libel has been instituted in London against Mr. Peter Anderson Graham, the author of a work entitled "The Perils of English Agriculture." In this book he charges that all the sanitary inspectors in England are corrupt, except perhaps one in fifty. A general accusation of this nature, not specifying the persons aimed at any more particularly, has usually been deemed by the courts insufficient to sustain a civil action for defamation.

The Lane Lectures for 1900.—The fifth course of the Lane Medical Lectures, inaugurated in Cooper Medical College in 1896, will be given in 1900 by Sir Michael Foster, professor of physiology, University of Cambridge, England. These lectures will be given on August 20th, 21st, 22d, 23d, and 24th, at 11 A.M. and 8 P.M. The subject of the lectures will be the history of physiology, each lecture being devoted to one or more of the great physiologists and to the discoveries connected with their names.

The Red Cross in China.—A phase of the trouble in China which may prove to be of great importance is the fact that the government of that country is not a party to the Geneva Red Cross Convention, by which the signatory powers bound themselves in time of war to respect the Red Cross, and to treat surgeons and nurses belonging to the armies of the enemy as non-combatants. It is thought possible that this fact may deter the War Department from permitting any of the women nurses who are being sent to the Far East from landing in China for duty there. There are nineteen female nurses on the transport *Grant* with General Chaffee, and five on the *Sumner* which sailed from San Francisco two weeks ago.

The Will of the Late Dr. John Ashhurst, Jr., disposes of an estate valued at $190,000. To the College of Physicians of Philadelphia are devised from his medical books a number not exceeding fifteen hundred volumes.

The New York School of Clinical Medicine.—We are informed that this school has not been discontinued, but six members of the teaching staff have resigned. Dr. Marcus Kenyon has been elected secretary of the medical board.

Mr. Wu Ting Fang was what might be called a little "previous," when last May he advised the graduates of a woman's medical college to repair at once to China in order to practise their profession in freedom and to their pecuniary advantage.

M. Pichon, the French ambassador in Pekin, was originally a medical student, but, discouraged at his want of success at the examinations, he relinquished medicine and took to journalism, for which he possessed a special talent. From journalism he passed into the political arena, where he has achieved a reputation which led to his being appointed to this important if somewhat perilous diplomatic post.—*The Medical Press.*

Philadelphia Mortality Statistics.—There were reported to the Philadelphia bureau of health for the week ending July 27th a total of 514 deaths, 50 less than for the preceding week, but 33 more than for the corresponding week of the preceding year. The heat still continues an important cause of death: 75 children died from cholera infantum, and 26 deaths were due to sunstroke, 27 to inflammation of the stomach and bowels, 31 to marasmus, 42 to pulmonary tuberculosis, 26 to heart disease, and 24 to pneumonia.

Gifts to a Hospital.—The managers of St. Timothy's Hospital at Roxborough, Philadelphia, have received $10,000 from J. Vaughan Merrick, Sr., who, with his late wife, originated the hospital as a memorial to their parents, by donating the house in which the hospital was opened in 1890. Of this amount $8,000 is for the extinction of a ground-rent and $2,000 for the endowment fund. The hospital has received also $5,000 from John H. Dearnley, to endow a free bed in honor of his daughter, and $50,000 from the estate of Perceval Roberts, Sr., for the erection of an annex now in process of construction.

Expert in Mental Diseases to be Sent to the Philippines.—In view of the cases of insanity liable to occur in such a large force as is now stationed in the Philippines, Surgeon-General Sternberg has decided to station an expert in mental diseases at Manila

to have charge of insane patients prior to their embarkation for this country. For this purpose he has given a contract as acting assistant surgeon to Dr. Charles H. Latimer, who has been a member of the staff of the government insane asylum at Washington (St. Elizabeth's) for the past twelve years. Dr. Latimer is a man of much experience and ability, and will undoubtedly be of great assistance in the general hospital at Manila in his special line of work. He takes with him as assistants two attendants from the government asylum for the insane, who have each had more than ten years' experience in the handling of cases of mental alienation.—*Boston Medical and Surgical Journal.*

Dr. John J. Brownson, of Dubuque, Ia., has been appointed president of the Dubuque County Board of Lunacy Commissioners. Dr. Brownson had charge of the West Dubuque asylum for eight years.

International Congress at Paris.—In addition to the Medical Congress, the opening session of which was held on Thursday of this week, the following, the proceedings of which are of more or less interest to physicians, have met or are to meet during the present summer. The Medical Press, under the presidency of Professor Cornil, July 26th to 28th; Professional Medicine and Medical Deontology, under the presidency of Dr. Lereboullet, July 23d to 28th; Medical Electrology and Radiology, under the presidency of M. Weiss, July 27th to August 1st; Public Assistance and Private Beneficence, under the presidency of M. Casimir Perier, July 30th to August 5th; Dermatology and Syphilography, under the presidency of Dr. Besnier, August 2d to 9th; Improvement of the Condition of the Blind, under the presidency of Dr. Dussouchet, August 5th; Deaf and Dumb, under the presidency of Dr. Ladreit de la Charrière, August 6th to 8th; Dental Surgery, under the presidency of M. Godon, August 8th to 14th; Pharmacy, under the presidency of M. Planchon, August 8th to 10th; Hypnotism, under the presidency of Dr. Voisin, August 12th to 15th; Aid in Time of War, under the presidency of M. A. Mézières, August 20th to 24th; Anti-tobacco, under the presidency of M. Decroix, August 20th to 25th; Pharmaceutical Specialties, under the presidency of M. Victor Fumonge, September 3d to 4th; Vegetarian Congress, under the presidency of M. Grand, June 21st to 23d; Homœopathic Congress, under the presidency of Dr. P. Jousset, July 18th to 21st; Accidents to Workmen and Social Assurance, under the presidency of M. Linder, June 25th to 30th; Physical Education, under the presidency of M. Léon Bourgeois, August 30th to September 6th; Chemistry, under the presidency of M. Berthelot, August 6th to 11th; Ethnology, under the presidency of M. Block, August 26th to September 1st; Conditions and Rights of Women, under the presidency of Madame Pognon, September 5th to 8th; Acetylene, under the presidency of M. Sebert, September 23d to 28th; Prehistoric Anthropology and Archæology, under the presidency of M. Al. Bertrand, August 20th to 25th; Sunday Rest, under the presidency of M. Bérenge, October 9th to 12th; Bibliography, under the presidency of General Sebert, August 16th to 18th. In the Congress of Comparative History, held from July 23d to 25th, under the presidency of M. Gaston Boissier, there was a section devoted to the history of science, including the history of hygiene in antiquity, the history of medicine in the Middle Ages, and the history of medicine among non-European peoples. In the Congress of Popular Traditions, to be held under the presidency of M. Beauquier, September 10th to 12th, popular medicine and magic are among the subjects to be discussed.

A Base Hospital for the Army in China.—It is uncertain as yet where the base hospital for the American army in China will be located. The choice lies between Nagasaki and Chefoo.

The Roentgen Society of the United States will meet in New York City, on December 13 and 14, 1900, at the Academy of Medicine. Papers have been promised by men in this country and Europe, and a very successful scientific meeting is anticipated. Unequalled advantages will be offered to the visiting members for instruction in *x*-ray work.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending July 28, 1900. July 19th.—(Orders issued by commander-in-chief of the Asiatic station.) Surgeon A. C. H. Russell detached from the *Newark* and ordered to the naval hospital, Yokohama, Japan, for treatment. Passed Assistant Surgeon R. M. Kennedy detached from the *Yorktown* and ordered to the *Newark*. Assistant Surgeon A. G. Grunwell detached from the *Brooklyn* and ordered to the *Monocacy*. July 21st.—Surgeons M. F. Gates and G. Rothganger commissioned surgeons from July 7, 1900. Passed Assistant Surgeon R. Spear commissioned passed assistant surgeon from June 22, 1900. Assistant Surgeon M. K. Elmer commissioned assistant surgeon from July 18, 1900.

Obituary Notes.—Dr. James M. McNulty died at his home in Santa Barbara. Cal., on June 22d. He was a native of New York State, and graduated at Geneva Medical College, N. Y., in 1846, going soon after as a surgeon in the Mexican War. Then coming to California, he was for some time in the employ of the Pacific Mail Steamship Company, then settling in San Francisco, where he practised for many years until 1889, when he partially retired to Santa Barbara. In 1861 he was surgeon of the First California Volunteers, and for the last two years of the war was medical director of the Second Army Corps.

Dr. Henry T. Herold, of Newark. N. J., died at his home in that city on July 25th, following an operation for appendicitis. He was thirty-eight years old, and was a graduate of the Bellevue Hospital Medical College in the class of 1887.

Dr. George Edelmann, who always asserted that he made the experiments that resulted in the discovery of chloroform, died at the City Hospital in St. Louis on July 19th. He was a graduate of Jefferson Medical College, and served as an army surgeon during the Civil War.

Progress of Medical Science.

Medical News, July 28, 1900.

Headache from Eye-Strain.—Casey A. Wood says that the site of the ocular headache in the order of frequency is: (1) the supra-orbital; (2) the deep orbital; (3) the fronto-occipital; (4) the temporal. The character of the pain is more likely to be dull and heavy than very acute. The exciting causes are tasks which require the use of the accommodation and convergence, reading, writing, drawing, painting, typewriting, sewing, music, card-playing, billiards, shopping, riding in trains and street-cars, etc. Long-sighted people suffer more from headache than the short-sighted. Insomnia, dyspepsia, pelvic disease predispose to ocular headache. The author is opposed to internal drug treatment, but advises very hot or very cold fomentations. In conjunction the following mixture may be rubbed over the forehead and temples, or a towel, wet with one part in ten with ice-water, may be laid over the closed eyes and forehead while the patient is lying down Spirits of lavender, alcohol, āā fl ʒ iii.; spirits of camphor, fl ʒ i. The author also suggests other remedies.

Acute Trional Intoxication.—Warren Coleman reports a case due to the ingestion of nine drachms in seventy-two hours. The patient recovered.

Aspiration in the Treatment of Acute Traumatic Empyema; with an Illustrative Case.—By Joseph D. Bryant.

A Contribution to the Management of Face Presentations.—By Malcolm McLean.

New York Medical Journal, July 28, 1900.

Some Observations upon Syphilitic Manifestations in the Uveal Tract: the Iris, Ciliary Body, and Choroid.—P. T. Vaughn says that during the past year seventy cases of syphilis have been seen by him exhibiting eye symptoms, and that of this number the uveal tract (iris, ciliary body, and choroid) was involved in twenty-nine, or 41.4 per cent. of the total number. He describes the symptoms of the different conditions found, quoting from various authors to substantiate his views, which are also supported by clinical histories of some of his own cases. He states among other facts that his own observation has been that the symptoms of plastic and serous iritis when due to syphilis vary little from the symptoms of these varieties of iritis when due to other causes. Pain is one of the most prominent symptoms, and it extends sometimes over the entire half of the head, corresponding to the branches of the supraorbital nerve. The pain is usually worse at night, and is always aggravated by bright illumination.

The Spectacle and Eye-Glass Habit.—N. B. Jenkins says that wearing spectacles or eye-glasses out-of-doors is always a disfigurement, often an injury, seldom a necessity. The old rule, "Wear glasses all the time," should be changed to "Wear glasses just as little as possible." Some wear spectacles for years, and then by lucky chance lose them, only to find that they get along better without. After wearing glasses only a few days many find the print looks worse to the naked eyes than before. This is a sure way to tell that glasses are wrong. Most people with troublesome imperfections of the eyes cannot leave their glasses off even for an hour or so without discomfort. This is because they have wrong glasses. The right glasses can be put on and taken off at any time with ease, and no more discomfort will follow than when putting on and taking off a hat.

Empyemas of the Accessory Nasal Cavities, with a Report of Cases in which the Antrum of Highmore was Involved.—R. A. Wright gives a general description of the affection, and reports five cases of antral suppuration. Concerning experimental puncture for diagnostic purposes he gives the following direction: A thick, large, straight aspirating needle is passed into the nose in the lower meatus underneath the inferior turbinated body, a little posterior to its middle half; the external end is pressed downward and toward the middle line, forcing the point up to the juncture of the inferior turbinated body with the lateral wall; the needle is now thrust through the bony partition into the antrum. This point of puncture is important, for in front of and below it the bony wall is too resistant to puncture with the needle.

Neurasthenia and Syphilis.—J. G. Kiernan mentions syphilophobia as a frequent source of neurasthenia. He advocates for this condition a familiar combination of gold with arsenic and the bromides.

The Pituitary Gland as a Factor in Acromegaly and Gigantism.—Concluding article by Woods Hutchinson.

Typhoid Fever in an Infant Eighteen Months Old; Recovery.—By A. Samuels.

Journal of the American Medical Ass'n, July 28, 1900.

Post-Febrile Insanity and its Treatment.—F. P. Norbury discusses nutritional changes as they affect the brain and infectious processes leading to mental disorder. Abnormal metabolism, he believes, permits oftentimes the entrance of infection. The writer quotes the conclusions of Mills, taken from the article in the "Twentieth Century Practice": (1) Specific infection must be included among the causes of mental diseases and of symptoms which precede, accompany, or follow febrile or other infectious disorders. (2) Much negative evidence can be adduced in favor of acute delirium being due to toxæmia. Such evidence is afforded by autopsies, which reveal neither gross nor histological lesions; and in these cases the toxæmia probably overwhelms the patient before the production of meningitis or other disease. (3) Analogies to nervous affections which are known or believed to be of microbic origin, such as multiple neuritis, myelitis, and chorea, favor the view that insanities with similar or related phenomena and lesions are also microbic in origin. (4) The evidence afforded by careful bacteriological investigations of acute insanity is thus far too meagre, but shows that various micro-organisms may induce the same or similar types of mental disease. (5) The mental disorders of pregnancy and the puerperal state are probably in a considerable proportion of cases toxæmic, without reference primarily to childbirth; but it cannot be regarded as proved that a bacillus of eclampsia or puerperal mania is a sole cause of these affections. He then discusses heredity, occupation, types, diagnosis, and treatment.

Exact Infant Feeding; Accidents and Incidents.—W. P. Northrup calls attention to the accidents which may arise from the very exactness of the methods employed. These may occur in mechanical ways. Scurvy may arise from the prescription for modified milk not being supervised and changed at the proper time. A safe method is to advance the proportions gradually to "full" undiluted milk. This may often be accomplished by the eighth month. To summarize: (1) Clean cow's milk, modified to some definite formula, is demanded. (2) A laboratory for modification is desirable; it secures greater exactness and cleanliness. (3) The physician should frequently revise his formula; frequent small percentages of increase are to be advised. (4) Accidents may arise from consigning an infant for several months to insufficient food ingredients. A baby is not the same baby for many weeks at a time, its growth and physiological demands change so much. Discussion follows.

The Prophylaxis and Management of Interstitial Nephritis.—C. W. Purdy says prophylaxis must include some definite knowledge of the tendencies of the patient to the disease under consideration. Histories of cases of purely acquired interstitial nephritis showed heavy appetites, sedentary lives, and excessive use of proteid food. The dominant factor is over-ingestion and over-elimination of nitrogen, and these furnish the key to prophylaxis. The disease is stamped in the strongest manner by heredity, and the family history furnishes a clew to a large proportion of cases suitable for prophylactic measures. Much can be done to prevent advanced cardiac complications. Abnormal friction in the circulation should be modified. Muscular tone can be improved by digitalis and strychnine. Absolute quietude is often required until heart tone is regained or restored to a measure equal to its work. When dropsy has set in diuretics have to be resorted to, but the fight from then on is a losing one.

Blood Examination.—M. H. Fussell directs attention to the value of blood tests to the general practitioner. He finds them quite as important as examinations of the urine, if not more so. They are of great value in obscure cases. All white-complexioned people are not subjects of anæmia, as tests will demonstrate. Conversely, a flushed face may disguise a decided reduction of hæmoglobin. The test is of value in showing when the patient has recovered. The clinical symptoms may very rapidly improve and still the blood count will show little change. Errors in reference to leukæmia and pernicious anæmia may be obviated. Cases in illustration are given. Fresh blood may be preserved for several hours by letting cedar oil run in under the cover-glass. Besides a microscope with oil immersion lens a hæmoglobinometer and hæmocytometer are required. The specimen is collected in a few minutes at the bedside and examined at leisure in the office.

Practical Physiology of the Digestive Organs.—A. L. Benedict describes details not well recognized or put down in textbooks having reference to digestive practice. The importance of mastication and insalivation is first considered, and then follows a study of the œsophagus and its rate of peristalsis (which in general is about eight seconds). The sounds of liquids passing through the cardia are best described as varying from a sharp squirting to a low gurgle. Free hydrochloric acid should form about half the

total acidity of the stomach contents. Numerous experiments show that the stomach contents do not change materially after withdrawal if cooled to 40° F. He is inclined to believe that there is exceedingly little absorption through the glandular membrane of the stomach; the potassium iodide test really marking the first peristaltic wave into the intestine.

Infant Feeding.—Alexander McAlister makes a plea for a closer adherence to and stronger advocacy of nature's method of infant feeding, on the part of medical men. He finds an alarming disinclination on the part of mothers to breast-nurse their offspring. Breast-nursed infants may not be fat, but they are usually robust and fleshy. Considering the chances for milk infection it is a marvel that the mortality of bottle-fed children is not vastly higher than it is. Koplik is quoted to the effect that even one breast-feeding in the twenty-four hours is of decided advantage, and he believes that "part breast is superior to all-hand feeding." Properly collected, cooled, and bottled milk is better than any laboratory milk.

Are Consanguineous Marriages Injurious to the Race?—Lawrence Irwell concludes that consanguineous unions are, in the great majority of cases, undesirable, not because they originate diseases *de novo*, but because they intensify existing disorders or diatheses from which very few families are exempt. They should not even be thought of in any family in which idiocy, insanity, epilepsy, congenital deaf-mutism, hare-lip, cleft palate, the phthisical or lithæmic diatheses have occurred, for all of these diseases or tendencies toward disease may be handed down from one generation to another. As it is not improbable that cancer is a micro-organic malady which attacks only those persons who have a proclivity toward it, families in which cancer has appeared, no matter how far back, should avoid consanguineous unions. Frequent marriages of persons whose environments have been very similar is injurious to the race, and extreme exclusiveness in marriage is not commendable.

Morbid Conditions Caused by Bacillus Aerogenes Capsulatus.—William H. Welch, in the Shattuck Lecture for 1900, reviews the history of the gas bacillus and recalls its diagnostic characteristics. It is distinguished from the colon bacillus by its power of producing gas abundantly in the blood, organs, and tissues of rabbits killed a few minutes after intravenous injection. Among the points distinguishing it from the bacillus of malignant œdema are the following: The malignant œdema bacillus is somewhat thinner, has greater tendency to grow into filaments, is less readily stained by Gram, produces spores regularly in culture media, is motile, liquefies gelatin more rapidly, produces a foul odor, produces less gas in lactose bouillon, peptonizes clotted casein, generates little or no gas in rabbits inoculated intravenously and then killed, and by subcutaneous inoculation in susceptible animals causes spreading bloody œdema with little or no development of gas bubbles, and appears after death in filaments on serous surfaces. The gas bacillus is widely distributed in nature, the natural habitat being the intestinal canal and the soil. It has been found repeatedly in Europe and America, and by Flexner also in Manila. The gas bacillus has been found in numerous conditions in human beings. Its presence in ordinary cadaveric decomposition is readily explicable by the occurrence of the organism in the healthy intestinal canal. Of a different nature, however, are the cases in which gas bubbles are found in the blood and organs within from one to eight hours after death and without any trace of putrefaction. There is every gradation from cases with a few bubbles of gas in the blood or tissues to those with extensive emphysema of the organs and tissues (Schaumorgane). The author has never found these gas bubbles unassociated with gas bacilli. The invasion in the majority of cases is from the intestine, but whether it and the development of gas occur ante mortem or post mortem has not yet been determined with certainty. The finding of gas bubbles within an hour after death offers no conclusive argument against the post-mortem invasion of the organism, and in the great majority of instances there is no doubt that the formation of gas bubbles is a post-mortem phenomenon. The bacillus is of interest to surgeons as well as physicians, since it is a frequent cause of that most dreaded of wound complications, emphysematous gangrene. It is probably not the sole cause, however, and the author is of the opinion that an aerobic bacillus, probably identical with Sanfelice's bacillus pseudo-œdematis maligni, is also capable of producing this affection. Among the uterine infections by the gas bacillus are mentioned emphysema of the fœtus, physometra, emphysema of the uterine wall, and puerperal gas sepsis. The bacillus has been found also in cases of puerperal endometritis in which there was no gas in the fœtus or the uterine cavity or wall. The urinary tract may not only be a portal of entrance for the gas bacillus into the circulation or adjacent tissues, but also be itself the seat of infection by this organism. In cases of pneumaturia the gas bacillus has been found in the bladder post mortem, and it has also been encountered in gas cysts in the renal pelves and in gas blebs under the vesical mucous membrane. These submucous and subserous gas cysts or blebs are among the most interesting of the lesions produced by bacillus aerogenes capsulatus; they have been found by Welch in the stomach, intestine, gall bladder and bile ducts, urinary bladder, renal pelvis, and vagina. The intestine is by far the most common source of the gas bacilli found together with gas bubbles in the blood and organs at autopsies. This invasion may occur either with or without definite intestinal lesions, and is probably in the majority of cases an agonal or post-mortem event. Especially demonstrative of invasion of gas bacilli from the intestine, usually post mortem, is the occurrence of gas bubbles limited to the neighborhood of the intestine, as in the intestinal wall, within the portal or mesenteric veins or lymphatics, in the subperitoneal tissue, mesentery, and omenta, around the pancreas, in the mesenteric glands, and especially in the loose tissue near the gall bladder and in the porta of the liver, without gas in more remote situations. Examples of each of these occurrences have been observed in very early autopsies without ordinary cadaveric decomposition. Among the infections in this class are local gastro-enteric lesions, pneumoperitonitis with and without perforation, and hepatic and biliary invasions. Pulmonary, pleural, and cerebral infections have also been observed, and the gas bacillus has been found in the blood during life.

The True Function of the State Medical Examining-Board.—By Allard Memminger.

The Lancet, July 21, 1900.

On Rupture of the Apparently Healthy Œsophagus.—E. J. McWeeny reports the case of a man aged forty years, who on entrance to hospital complained of pain in the lower parts of the chest and emphysematous swelling of the neck and face, which later mounted to the eyelids and extended down the thorax. His general condition was one of collapse, and he died seven hours after admission. He had been a heavy drinker and was much given to "dry retching." Autopsy revealed a slit-like aperture in the œsophagus nearly 1.5 cm. long, in the anterior surface just above the diaphragm. The writer analyzes seventeen similar cases, giving a full bibliography and emphasizing the salient points of each. He concludes that the two main factors that are operative in causing rupture of the macroscopically normal gullet are (*a*) softening of the coats and (*b*) sudden increase of pressure from within. The softening is due partly to intra-vital digestion, and partly to inflammatory infiltration. The intra-vital digestion is to be accounted for by (*a*) circulatory disturbance, which in his case took the form of venous thrombosis, and (*b*) prolonged sojourn of peptic matters in the gullet from prolonged retching. The increased pressure from within is doubtless ascribable to the violent propulsion of the gastric contents into the lower part of the gullet, while its upper outlet is obstructed by the contracted state of the muscle—in other words, to want of co-ordination of the muscular action of the tube, probably due to exhaustion from prolonged overactivity. Whether a localized phlegmonous œsophagitis—for that is the condition which existed in the case now recorded—is a constant factor in these cases, it is of course impossible to assert in the absence of microscopical details of the other cases.

A Case of Pernicious Anæmia following on Traumatic Stricture of the Small Intestine.—The patient of A. E. Bar-

ker was a man who had been run over by a wagon seven years previously, and had ever since the accident suffered from periodic attacks of pain and vomiting. Analysis of the blood showed red cells, 2,000,000; white cells, 54,000; hæmoglobin, thirty per cent. Symptoms of intestinal obstruction were developed, and an abdominal incision was made. A stricture was found in the first part of the jejunum, and an anastomosis was made of the parts above and below. The patient did not do well after the operation, and died on the second day. The autopsy was made by W. Hunter, who summarizes the features of the case as follows: (1) A man, temperate, well fed, and living in healthy surroundings. (2) bad teeth causing alternately alveolar and ethmoidal suppuration without at any time occasioning local discomfort; (3) he always suffered from "heartburn" (denoting chronic gastric catarrh with diminished acidity of gastric juice); (4) accident causing stricture of jejunum; (5) more or less severe abdominal and gastric symptoms lasting six years; (6) more or less rapid supervention of the features of pernicious anæmia nine months before death; (7) post mortem (*a*) dental decay with local complications—*e.g.*, alveolar and ethmoidal suppuration, and (*b*) definite infection (coccal and streptococcal) of the mucosa of the intestine and colon, with definite catarrhal, inflammatory, and necrotic changes—to a less extent of the stomach.

The Varieties of Acute Pneumonia.—H. Hanford discusses some of the unusual forms of pneumonia, calling special attention to cases with low temperature and cases in which the symptoms both general and special are well marked and undoubted, but in which physical signs are scanty or absent. Some of these have been explained on the theory that the area affected is central, not reaching the surface of the lung. In other cases it has been suggested that the general symptoms have been caused by the toxins of the pneumococcus growing in other than the pulmonary organs. The symptoms are due not only to the local lesions but in great part to the specific nature of the poison. The author also discusses the question of infection in pneumonia, food pneumonias, and those cases seen in connection with the grippe and the plague.

A Case of Ulcerative Endocarditis with Recovery under the Use of Antistreptococcic Serum.—The patient of J. M. Clarke was a girl aged twenty-two years. The diagnosis of ulcerative endocarditis was made on the following grounds: (1) The presence of a chronic valvular lesion on which an infective process is apt to graft itself; (2) the fact that the illness did not yield to the several salicylic compounds which were tried in full doses without effect; (3) the occurrence of a pulmonary infarct; and (4) the steady progress of the patient from bad to worse until treatment by serum was begun, which treatment again would have had no influence on acute rheumatism. No special features were noticeable after the injections other than have been reported from their use in other maladies. At first there were noticed local pain, urticaria at the site of injection, and slight swelling, but later only malaise for several hours and headache were felt.

The Ethics of Secrecy in the Learned Professions.—C. R. Straton compares the customs of the past with those prevailing and the rules of action in England with other countries relative to the confessions made to attorney, physician, or priest. The surgeon's evidence often being essential to the establishment of facts upon which justice can be based, it is held that excluding the physician from the witness stand often interferes with the proper administration of justice. Professional secrecy has reached a higher development in France than elsewhere, and a brief sketch of its evolution and operation is given. Possible changes in the law of England are considered, the tendency of the times being not to exclude any evidence which may lead to justice. A plea is made for an observance of the moral proportion of things, and a note of warning is sounded before the medical profession drifts into the doctrine of absolute secrecy under all circumstances. Safeguards should be devised to prevent ourselves from being made the passive agents of injustice and wrong.

The Alleged Increase in Insanity.—R. H. Noott thinks that the reported increase in insanity of late has been due to faulty statistical methods. A calculation based on a recently published table shows that in the year 2301 every one will be mad. There has been during the past ten years in England an unusually rapid accumulation of registered lunatics, but this is not held as proving that the actual number has increased, and is to be explained in more complete registration, greater confidence in asylum treatment, etc. Intemperance prevention, and cure are considered from various sides.

The Preliminary Education of Medical Students.—P. Q. Karkeer is of the opinion that the present standard of scholarship required in the preliminary examination is not a sufficient indication that the candidate for entering the medical profession has received the education of a gentleman. He discusses the best ways of developing a boy's faculties by educational training, pointing out what is best for the student and what best for the profession.

Münchener medicinische Wochenschrift, July 10, 1900.

A Contribution to the Knowledge of the Action of Oil of Turpentine.—Schulz, supplementing former studies on other drugs, has conducted a series of observations on the action of minimal doses of oil of turpentine. Two sets of experiments were conducted, the one with an alcoholic solution containing one per cent. of the drug, the other of a strength of 1 : 1,000. In either case the daily dose was twenty drops of the solution given in the morning. The results of this almost homœopathic medication were very pronounced. The central nervous system gave evidence of great depression; there was more or less hebetude, with disinclination to mental and physical exertion, and extreme muscular fatigue. Nearly all the experimenters suffered from insomnia. The effect on the gastric system was characteristic. During the first few days eructation was complained of; later this disappeared, but gastric pains of greater or less severity supervened. There were vomiting, anorexia, and constipation. The urine in all cases acquired a noticeable odor and became dark-colored; albumin was not present. The pulse, contrary to most published observations, was found to be depressed in frequency. In two cases a well-marked facial acne was caused.

A Case of Hysterical Dumbness the Result of Intoxication.—Bloch describes the case of a boy, fifteen years old, who while at work in a carpenter shop suddenly fell to the ground unconscious. On examination the eyes were found wide open, pupils dilated and reacting to light; neck, arms, and legs rigid and resisting efforts at flexion; patellar reflexes exaggerated. The patient did not reply when questioned; the mouth was firmly closed, and medication by that channel was impossible. The temperature was normal; pulse 70. For two days this condition continued unaltered; on the third the patient was able to indicate his wants by writing, and finally, as the result of suggestive and local treatment, on the sixth day he regained complete control of all his faculties. The author considers the case of particular interest, since the only cause that could be found for the trouble seemed to lie in the fact that the stove in use in the shop was not in good order, and that on the same day the patient was affected several other workmen complained of various symptoms, headache, nausea, etc., and he believes that these, as well as the patient's attack, were due to carbonic-oxide poisoning.

Dressings Left Behind after Laparotomy.—Wunderlich adds two more to the instances in which dressings, etc., have been unwittingly left behind after laparotomy. In the one case, three and one-half months after making an uneventful recovery from the operation the patient voided with the fæces a compress eight inches wide by forty inches in length. No bad effects followed. In the other case the patient succumbed to cardiac collapse thirty-six hours after a cholecystectomy; at the autopsy a cloth of the size of a small handkerchief, such as had been used for packing, was found free in the peritoneal cavity, there were no evidences of peritonitis. The author adds the trite comment that he now counts the instruments, pads etc. himself.

The Etiology of Fibrinous Bronchitis.—Ott reports a case of this uncommon disease, and gives in *résumé* the various theories that have been advanced concerning its causation. In the case of his own patient, a knife-grinder there were found in the sputum the pneumococcus of Fraenkel and the staphylococcus pyogenes aureus, and in the author's opinion the localization of the trouble in the bronchi was due to the continued irritation caused by the inhalation of the metallic particles attendant on the occupation, while

the protracted course of the disease was due to the mixture of micro-organisms.

Contributions to the Study of Immunity.—By Dungern.

A Case of Weil's Disease.—By Schottenhelm.

Berliner klinische Wochenschrift, July 9, 1900.

A Constant Bacteriological Result in Scarlatina.—A. Baginsky and P. Sommerfeld conclude a series of articles with the following propositions. (1) In all cases of scarlatinal angina we find streptococci, sometimes in pure culture, generally, however, accompanied by other cocci, but always overshadowing them. (2) In all the fatal cases (forty-two) of scarlatina examined, a streptococcus was found in all the organs and also in the blood and bone marrow. From this it is safe to conclude that it is constantly present in all cases of scarlatina. (3) The streptococcus reveals itself in its morphological, cultural, and biological relations as do the streptococci of writers in general. With all methods of differentiation hitherto used it is not capable of being distinguished. (4) The streptococcus is of varying degrees of virulence, and this can be increased by successive cultures. It develops a toxin in the culture medium. (5) Specific peculiarities of the streptococcus found in scarlatina cannot be developed by culture methods any more than is the case with the streptococci heretofore described. (6) The constancy of the presence of this streptococcus in fatal scarlatinal cases makes the same significant as a factor in the disease. (7) The collective clinical manifestations of scarlatina are due to the spread of the streptococcus in the organs (infection) and the poison derived from its life processes (toxicity).

Extirpation of a Fibro-Lipoma in the Retroperitoneal and Pelvic Connective Tissue.—F. Konig reports the case, which occurred in a man aged forty-four years, who died of sudden heart failure eight days after operation. The mass rose as high as the ensiform process, and the diagnosis before operation lay between some form of rapidly growing tumor of unknown nature and tuberculous peritonitis. Bibliographical reference is made to several similar cases previously reported.

The Present State of Bacteriology.—By Baumgarten.

The Pathology of Morbid Tumors.—By O. Israel.

Deutsche medicinische Wochenschrift, July 12, 1900.

Some Contributions to the Pathology of Influenza.—A Wasserman was surprised to find that the influenza epidemic which lasted through the first three months of this year differed notably from the great pandemic of 1890, especially in its bacteriology. In the earlier epidemic the bacilli assumed to be the specific cause of the disease were constantly to be found in great numbers in the sputum, and the production of pure cultures was a simple and easy matter. In the cases observed this year, however, it was at first found extremely difficult to demonstrate the presence of any bacilli at all, and further study revealed the fact that though invariably present early in the disease they disappeared with great rapidity, so that often as soon as twenty-four hours after infection none was to be found. Linked with this phenomenon of the early and complete disappearance of the micro-organism was the occurrence in many of the cases studied of symptoms of severe intoxication, syncope, cardiac weakness, etc. To explain these facts the author advances the theory that every infectious disease confers a certain degree of immunity, and that even epidemic influenza protects its victims for a certain length of time; thus no case is recorded of any one individual's having the disease twice in the same epidemic. It therefore follows that there are present in the blood of these individuals immunizing principles, which, although not strong enough to resist infection, yet cause the speedy destruction of the bacilli. As a result of this sudden dissolution of the germs there is liberated an overwhelming amount of toxin with which the system is unable to cope, hence the serious nature of the symptoms. The author's belief is that a large number of the patients in whom the disease now runs an anomalous course have been partially immunized in the great pandemic of ten years ago, and, furthermore, that the conditions are rapidly growing more and more favorable for a repetition of that historical event.

Experiences with Phototherapy (Conclusion).—Strebel's article presents his ideas on the value of this mode of treatment after having given it extended trial in a large number of cases. In general his opinions are favorable to the method, though in nearly every instance he ascribes almost as much value to the heat produced and the consequent diaphoresis as to the direct effect of the light rays themselves. Both arc and incandescent lights are used, but preference is given to sunlight as being more efficacious and cheaper; its disadvantage is that it is not always available when desired. Obesity is one of the affections in which the light baths seem of especial service, others in which they have been tried with more or less success are, chronic rheumatic and gouty conditions, nephritis, heart lesions of various sorts, diabetes, in which they seemed to act particularly well, anæmia, chronic catarrhal and emphysematous affections of the respiratory system, sciatica, hard and soft chancre, leg ulcers, and furunculosis. The action of the light pure and simple is perhaps best shown in cases of lupus vulgaris. Here the remarkably satisfactory results can be due only to the direct bactericidal action of the concentrated rays on the bacilli situated just beneath the surface. It is the author's belief that further investigation and clinical testing will reveal a definite sphere of usefulness for this plan of treatment and accord it a permanent place among the list of therapeutic agents.

The Differential Staining of Malaria Parasites.—Ruge recommends the following technique. The smear is to be made by touching the edge of a cover-glass to the drop of blood, and having placed this edge in contact with a slide it is to be inclined at an angle of 45° and pushed slowly and evenly along the surface of the slide in such a way that the blood lies behind the advancing edge, *i.e.*, is drawn along after it and not pushed before it. The preparation is to be dried and fixed in absolute alcohol, and is then ready for staining with the following solution. To 100 c.c. of water 0.2 gm. of soda is added, and the solution is heated. While boiling 0.3 gm. of methylene blue is stirred in, and the stain is filtered forty-eight hours later. A few drops are to be poured on the slide and immediately rinsed off with water. The red blood cells will be found stained yellowish or bluish green, the ring forms of the parasites blue-black, the larger forms grayish-blue or dark blue, and the nuclei of the white cells intensely blue.

Enucleation of the Eye, its Substitutes, and its Relation to Sympathetic Ophthalmia.—By Schmidt-Rimpler.

A Contribution to the Knowledge of Meningo-Typhoid.—By Hofmann.

French Journals.

The Value of Organic Protective Coverings.—J. C. Platon and O. Platon relate an instance of severe burn treated by covering with strips of the shell membrane of a freshly laid egg. Over this was laid a sheet of sterile tinfoil as a protective to the membrane. After five days the egg membrane was intact, and beneath it there were island-like whitish dots of epidermis. Cicatrization was complete in eight days. The method, first proposed by Amat in 1895, was described at length by Max Schiller, who is quoted, and the views of many observers bearing upon the question of protective dressings are given.—*Gazette des Hôpitaux*, July 12, 1900.

Treatment of Aneurisms with Gelatin.—Lancereaux and Paulesco have since reporting two cases applied the gelatin treatment to a number of others, four of which they now report, together with a review of the treatment as it has been carried out by others. They conclude that rest in bed is not sufficient for the cure of aneurisms of the aorta, as Litten has claimed. Complete cure of a large aneurism by total obliteration of the sac is obtained only after a variable number of injections of gelatin according to the case, but approximately from twenty-five to thirty at the least.—*Gazette des Hôpitaux*, July 17, 1900.

The Pathology of Human Milk.—John Zahorsky says milk must be studied as a modified tissue having its pathological variations. In volume it is subject to atrophy and hypertrophy; in structure it may show pathological degenerations. In galactorrhœa we have a hypersecretion, in oligo-galactia a deficient secretion due to inherent weakness of glandular activity in some instances, in others contributed to by irregular nursing, etc., or weakness of digestion and metabolism may be at the root. Pathological changes in proteid percentages are common. Instead of an early showing of two per cent., proteids may be present in percentage of two and a half to three and a half, and decrease but little as lactation proceeds. A connection may be traced between this high percentage of proteids and intestinal colic due to gases so frequent in infants. Artificial foods containing carbohydrates which inhibit proteid decomposition often prevent these colics, just as does dextrinized gruel as a diluent for mother's milk. Every effort should be made to preserve the mammary secretion, and the child is to be taken from the breast only as a last resort.—*St. Louis Courier of Medicine*, July, 1900.

Reviews and Notices.

Diseases of the Gall-Bladder and Bile-Ducts, Including Gall Stones. By A. W. Mayo Robson, F.R.C.S., Senior Surgeon to the General Infirmary at Leeds; Emeritus Professor of Surgery in the Yorkshire College of the Victoria University; Member of Council and Hunterian Professor of Surgery and Pathology at the Royal College of Surgeons of England, Assisted by Farquhar Macrae, M.B., C.M. (Glas.). Second edition. Pp. 313. New York: William Wood & Company. 1900.

This well-known work on the surgery of the gall bladder and bile ducts appears much improved in its second edition; the lecture form has been abandoned for the more readable narrative, and certain interesting additions have been made, among which may be mentioned those on membranous cholecystitis and on gall stones. To his original series of one hundred and seventy cases the author has added one hundred and thirty-five, and has rearranged the whole number under the various headings to which they separately belong. The book is authoritative and comes from the ripe personal experience of a successful operator. It is well illustrated with diagrams and plates taken from the original and is most interesting throughout. There is a complete list of the operations done, with date, age, sex, description of the case, result and after history, which is a great help to one wishing to study them in detail.

Contributions to the Science of Medicine. Dedicated by his Pupils to William Henry Welch on the Twenty-fifth Anniversary of his Doctorate. Pp. 1,066. The Johns Hopkins Press, Baltimore. 1900.

To review the contents of this volume would take many pages, for the articles are numerous. Among the articles we notice the following. "A Contribution to the Study of the Pathology of Early Human Embryos," by Franklin P. Moll; "On Urea in Some of its Physiological and Pathological Relations," by C. A. Herter; "The Direct Action of Nicotine upon the Mammalian Heart," by H. G. Beyer; "The Effects of Shaking upon the Red Blood Cells," by S. J. Meltzer; "The Blood-vessels, Angiogenesis, Organogenesis, Reticulum, and Histology of the Adrenal," by J. M. Flint; Specific Degenerations of the Cortical Arteries," by H. J. Berkley; "The Regeneration of the Crystalline Lens," by R. L. Randolph; "The Histology of Acute Lobar Pneumonia," by J. H. Pratt; "Bilateral Cholesteatomous Endotheliomata of the Choroid Plexus," by George Blumer; "Concerning the New Formation of Elastic Fibres, Especially in the Stroma of Carcinomata," by H. U. Williams; "Cirrhosis of the Liver of the Guinea-pig Produced by a Bacterium and its Products," by G. H. Weaver; "On the Muscular Architecture and Growth of the Ventricles of the Heart," by J. B. MacCallum; "Some Observations upon the Surgical Anatomy of the Gall-bladder and Ducts," by G. E. Brewer; "A Case of Plexiform Neuroma of the Eyelid," by Harry Friedenwald; "A Case of Multiple Myeloma," by J. H. Wright; "The Development of the Musculature of the Body Wall in the Pig," by C. R. Bardeen; "A Rare Variety of Adenocarcinoma of the Uterus," by T. S. Cullen; "A Bacteriological and Microscopical Study of Over Three Hundred Vesicular and Pustular Lesions of the Skin with a Research upon the Etiology of Acne Vulgaris," by T. C. Gilchrist; "The Frequency and Significance of Infarcts of the Placenta, Based upon the Microscopic Examination of Five Hundred Consecutive Placentæ," by J. Whitridge Williams; "A Contribution to the Knowledge of the Bacillus Aerogenes Capsulatus," by W. T. Howard; "On the Intravascular Growth of Certain Endotheliomata," by W. G. MacCallum; "The Cultivation of Amœbæ," by Caspar O. Miller; "The Bacillus Pseudo-Tuberculosis Murium," by Dorothy M. Reed; "Experimental and Surgical Notes upon the Bacteriology of the Upper Portion of the Alimentary Canal, with Observations on the Establishment There of an Amicrobic State," by Harvey Cushing and L. E. Livingood; "The Origin, Development, and Degeneration of the Blood-vessels of the Human Ovary," by J. G. Clark, The Gonococcus," by H. H. Young; "The Histogenesis of the Cellular Elements of the Cerebral Cortex," by Stewart Paton; "Experimental Pancreatitis," by Simon Flexner; "Chronic Hypertrophic Gastritis of Syphilitic Origin Associated with Hyperplastic Stenosis of the Pylorus," by J. C. Hemmeter; "A Case of Adenocarcinoma which Originated in the Submucous Glands of a Trachea-like Formation Found in a Sacral Teratoma," by W. H. Hudson; "On Hydromyelia, in its Relation to Spina Bifida and Craniochisis," by E. B. Block; "Experimental Disseminated Fat-necrosis," by E. L. Opie; "Multiple Hyperplastic Gastric Nodules Associated with Nodular Gastric Tuberculosis," by Claribel Cone, "On Serum Substitutes with Special Reference to Asiatic Cholera," by Arthur Blackstein; "Endocarditis Due to a Minute Organism, Probably the Bacillus Influenzæ," by Mabel F. Austin; "On the Microscopic Alterations Met with in the Tissues from a Case of Chronic Diffuse Nephritis, Terminating with Symptoms of Landry's Paralysis," by L. F. Barker, "Model of the Medulla, Pons, and Midbrain of a New-born Babe," by Florence R. Sobin, "A Contribution to the Surgery of Foreign Bodies," by W. S. Halstead. The illustrations are exceptionally fine and very numerous, many of them in colors, and as a frontispiece there is an excellent heliotype portrait of W. H. Welch.

Home Nursing. By Eveleen Harrison. New York: The Macmillan Co. 1900.

This is an elementary work for mothers and others on modern scientific methods of caring for the sick, and as such will fill a place in the household library. Nurses will find in it many useful hints and practical points, especially in the preparation of foods and delicacies for the sick-room and during convalescence. Receipts are grouped according to the diseases.

The International Medical Annual and Practitioner's Index. A Work of Reference for Medical Practitioners by American and Foreign Contributors. (Eighteenth Year.) New York. E. B. Treat & Co. 1900.

The fields of medicine and surgery including the collateral branches are here reviewed in a comprehensive practical manner for quick reference. Condensed original articles by able writers have been selected with care. A good feature of the work is the rather full synoptical index, and the alphabetic arrangement is well suited to the reader's requirements. New remedies are first considered, then new modes of treatment, and these are followed by notes on legal decisions and sanitary science. The print is small, so that a vast amount of material is crowded into the work. All the new things that have come up during the year have received some recognition in one part or another of the annual.

Essentials of Medical Diagnosis Arranged in the Form of Questions and Answers. Prepared especially for students of medicine by Solomon Solis-Cohen, M.D., Professor of Clinical Medicine and Therapeutics in Philadelphia Polyclinic; Lecturer on Clinical Medicine in Jefferson Medical College; Physician to the Philadelphia Hospital and to the Rush Hospital for Consumptives, etc., and Augustus A. Eshner, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic; Physician to the Philadelphia Hospital, etc. Illustrated. Saunders' Question Compends. No. 17. Second edition, revised and enlarged. Pp. 417. Philadelphia W. B. Saunders, 925 Walnut Street. 1900.

This is an excellent book for students, inasmuch as it presents the essential outlines without distracting detail, thus affording a good ground work which can be supplemented later by more comprehensive works. The second edition differs from the first chiefly in being enlarged and brought thoroughly up to date. The more common views of the profession are set forth fully, while the less accepted views are properly omitted. The book is not a simple compilation, like so many of the smaller works on medicine, but presents the experiences and knowledge of two well-known clinicians.

Medicine and the Mind (La Médecine de l'Esprit). Translated from the French of Dr. Maurice de Fleury by Stacy B. Collins M.D. (U.S.A.). With fourteen figures and diagrams. London Downey & Co. New York Charles Scribner's Sons. 1900.

This work received the Bordin prize at the French Academy, and as such merits our respect and attention. The subjects treated deal chiefly with problems in modern scientific psychology in an entirely new way, and although we cannot agree with the author in all instances and, moreover, do not accept all his dicta as proven, still he has opened a new field from which the future may and probably will derive some benefit. The most interesting and novel chapters are those which deal with the problems of human fatigue and strength, of indolence and melancholy, and the therapeutic measures adaptable to each. The rather material explanation of differences in blood pressure causing these different emotional states is not, however, entirely satisfactory, and the consequent method of treatment by his "artificial serum" is not one which we think devoid of the suggestion element which is so well recognized. The work should be read by all physicians who are interested in medico-legal medicine or psychology.

Section on Hygiene and Sanitary Science.—The Section on State Medicine of the American Medical Association will hereafter be called the Section on Hygiene and Sanitary Science.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

WEATHER—PATHOLOGISTS AT CAMBRIDGE—TROPICAL DISEASES—MALARIA AND MOSQUITOS—QUESTIONS OF NOMENCLATURE—ARSENIC IN SODII PHOSPHAS—ST. PANCRAS LUNACY INQUIRY—MR. COUTTS—SUNDAY FUND—THE ROYAL ARMY MEDICAL CORPS—SMALLPOX—BRITISH MEDICAL ASSOCIATION.

London, July 13, 1900.

Last week while we were reading of your sufferings under a heat wave we were shivering and complaining that summer seemed about to omit its visit to our islands. I was glad of a fire in my consulting-room up to Monday, but on Tuesday a welcome change set in—summer put in an appearance, and the next day and yesterday people were greeting each other with the whimsical expression "beastly fine weather." To-day it is two or three degrees cooler by the thermometer, but people feel the heat as much. Not that it is abnormal—80 to 83° F., falling in the evening into the seventies. I find this merely comfortable warmth to what you have experienced. Storms have been severe in northern districts and are anticipated here.

The Pathological Society's visit to Cambridge on the invitation of Prof. Sims Woodhead came off as announced on the 30th ult. Professor Osler, of Baltimore, was invited to preside and took the chair, and interesting communications were made, for which a vote of thanks was accorded, as well as one to the chairman, to Dr. Woodhead, and to the university authorities.

Prof. S. A. Flexner, of Philadelphia, said that an acute and a chronic form of tropical dysentery occurred in Manila. The former might terminate in forty-eight hours or become chronic. The chronic *per se* was amœbic and commonly followed by hepatic abscess; not so the chronic following acute. The acute disease was not amœbic, but a bacillus very much like that of typhoid had been isolated. It seemed identical with that from the endemic dysentery of Japan.

Professor Flexner also made some critical remarks on the bacteriology of yellow fever. The fatty degenerations of the viscera produced by the supposed bacillus of the disease were also produced by other organisms.

Dr. G. H. F. Nuttall gave a demonstration on the relation of mosquitos to malaria. He showed some live Anopheles maculipennis which he had caught in the neighborhood of Cambridge. He illustrated with specimens, micro-photographs, and drawings the changes undergone by avian and human parasites in the species of Culex and Anopheles respectively. Maps showing the distribution of malaria and Anopheles were exhibited. There was an agreement between the former distribution of malaria in England and the present distribution of Anopheles (A. maculipennis, A. bifurcatus, A. nigripes), but further details on this point were promised. It seems curious in some respects that Anopheles persist in England although malaria has practically disappeared. The fact suggests further research

Dr. Cobbett showed cultures of the diphtheria bacillus obtained from the nasal discharge of a pony. He also described experiments showing that diphtheria toxin is excreted in the urine of animals—even from some which are relatively insusceptible.

Dr. J. W. H. Eyre remarked on the influence of the medium on organisms cultivated on it, and urged the adoption of a definite standard reaction in our laboratories similar to that used in America. He said litmus paper and solution were alike unsuitable, and recommended phenolphthalein as sensitive and satisfactory.

Questions of nomenclature are interesting enough to many, and yet not seldom vexatious or even puzzling, especially when relating to a specialty. Surgeons and gynæcologists have rivalled each other in the combination of similar syllables for dissimilar proceedings, and questions of priority have often been mixed up with those of nomenclature. Take an example or two. Dr. A. Routh read a paper at the meeting of the Obstetrical Society on "Porro-Cæsarean Hysterectomy," in which he discussed the advantages of the modern Porro operation over the "Sänger-Cæsarean." Dr. Galabin objected to his nomenclature, and proposed "Baer's operation," or "Cæsarean hysterectomy," or "Cæsarean panhysterectomy," as the case might be. Dr. W. Duncan thought the operation described by Dr. Routh might be properly called "abdominal hysterectomy of the gravid uterus." This at least has the merit of conveying some idea to those who do not follow the specialty. Dr. Horrocks objected to the term "Sänger-Cæsarean section," as the essential part of Sänger's operation is now generally discarded. Dr. Spencer hoped that whatever name might be adopted for hysterectomy of the pregnant uterus, it would never be called Baer's operation, for Baer had no claim to it and did not make any claim himself.

Another allied question was lately discussed at the Royal Academy of Medicine in Ireland—and that in the obstetrical section. Dr. H. Jellett read a paper on "The Dublin Method of Effecting the Delivery of the Placenta," in which he maintained that Credé only arrived independently at a method which had been taught in Dublin from time immemorial. He introduced it in Germany without a suspicion apparently that it had long been the familiar plan in Dublin, and so it got associated with his name and is still spoken of as his method. Various writers were cited in proof of this, and the term "the Dublin method" was pronounced to be the correct one. Dr. Smyly said there was a distinction between the two methods, and Credé's was inferior because it was too active. Spiegelberg, who had observed both methods practised by those responsible for them, declared the Dublin to be superior, as it waited till the placenta had been expelled from the uterus and then expelled it from the vagina. Credé's was too active, for by expelling the placenta too soon they might leave portions behind, leading to post-partum hemorrhage and subinvolution.

Dr. Smyly raised yet another question of the kind. He said the method of preserving the perineum commonly called von Ritgen's undoubtedly originated in Dublin. The credit of this seems likely to be lost by the Dublin school, and these questions show the inconvenience of attaching a man's name to a procedure as soon as he writes a paper about it, whether original or not.

By a curious coincidence the subject of nomenclature has also been discussed at Edinburgh, and again by the accoucheurs. At the Edinburgh Obstetrical Society on the 13th ult., Dr. Berry Hart read a paper on "the nomenclature of transverse presentations and of version." He divided the former into "dorso-anterior" and "dorso-posterior" positions, and each of these again into left and right "acromio-iliac." "Scapulo-anterior" and so on was concise but not so good. The varieties of version he preferred were "Simpson's combined," "Hicks' bipolar," and "combined external." The last is cephalic—the other two are podalic.

A chemical manufacturer here lately called in all the sodii phos. effervesc. which he had sold, because he found it contaminated with a dangerous amount of arsenic. So far no injury has been done, but it would have been well for him had the tests been made before sending the drug out. Most samples of sodium phosphate contain some arsenic derived from the sulphuric acid employed in the manufacture. Commercial oil of vitriol is often loaded with arsenic which appears in the sodium phosphate as arsenate. This being isomorphous with the phosphate cannot be removed by recrystallization. Professor Tichborne says many specimens, if hurriedly tested, might seem slightly impure although loaded with arsenic, as the arsenic does not readily come down as a sulphide. He adds that commercial sodium phosphate is only fit for manure, and the pharmacopœia process should be discarded, the salt for medicinal purposes being obtained by the interaction of phosphoric acid and sodium carbonate.

The inquiry into the St. Pancras lunacy scandal is bringing out disagreeable facts. The relieving officers have confessed to a system which is no less than bribery, and the public is demanding radical changes.

Mr. Burdett-Coutts has shown his "common sense" by objecting to Professor Cunningham as one of the committee to inquire into his allegations, because, forsooth, the professor is an examiner of army surgeons.

The Hospital Sunday Fund on Wednesday had amounted to more than £40,000.

Some cases of smallpox have occurred in London, giving rise to alarmist reports of the usual kind.

An extraordinary general meeting of the British Medical Association has been called for next Wednesday, when a draft of new regulations effecting considerable changes in the constitution will be proposed by the Council, and if carried will be submitted for confirmation at the forthcoming annual meeting at Ipswich on August 2d.

Out of seven hundred and thirteen fellows who voted at the late election at the College of Surgeons only thirty-four attended personally—a clear indication that the postal system is essential. Its adoption may lead to a more liberal policy.

Surgeon-General Muir, deputy director-general of the Army Medical Department, and Col. Egerton Saunders have received the decoration of C.B.

Many more surgeons and nurses are going to the front, and with three wars upon us the demands for the army and navy medical services must increase. So, too, must the losses.

Dr. FitzHugh has died at the Yeomanry Hospital, where he did excellent work. He was only twenty-eight years old.

Professor Oyston, of Aberdeen, is down with typhoid at Bloemfontein, but by last telegrams was progressing favorably.

Therapeutic Hints.

Irritable Bladder.—

℞ Salol,
Tinct. hyoscyami.....āā ʒ ij.
Infus. buchu.....ad ʒ vi.
M. S. Tablespoonful three times a day.

—Fothergill.

Gout.—

℞ Ext. colchici acet.,
Ext. rhei,
Ext. aloes soc.....āā gr. xij.
Ext. belladonnæ.....gr. ij.
M. ft. pil. No. x. S. One at bed-time twice a week.

—Garrod.

In Threatened Uræmia.—

℞ Pilocarpin.....gr. i.
Ac. hydrochl. dil.....ʒ ij.
Aq. destil.....ʒ ij.
M. S. Teaspoonful every three hours.

Acute Cystitis.—

℞ Ext. hyoscyami,
Ext. cannabis indic.....āā 0.4
Sacch. alb.....5.0
M. ft. chart. No. xii. S. One three times a day.

—Ultzmann.

Salicylate Mixture.—

℞ Sodii salicylat.....4–8 gm.
Curaçao.....60 "
Aq. destil.....90 "
Syr. aurant cort. amar.....60 "
To be taken in twenty-four hours with Vichy water.

—*Lyon Méd.*, May 20th.

Neuralgia, especially when acute, is benefited by a dose of one or two ounces of castor oil in ale containing considerable gas, administered before breakfast.—H. M. Moyer.

Epilepsy.—Santonin gives better results than bromides, and acts when the latter fail or are not well borne. It is free from injurious effect, especially the production of melancholia, mental hebetude, depression, eruptions, etc.—Lydson.

Morphine and Alcohol Habits.—

℞ Ammon. brom.....gr. v.
Ext. bellad. fld.,
Ext. nuc. vom. fld.,
Ext. cannabis ind. fld.....āā ♏ ij.
Aquæ.....ad ʒ ij.
M. S. At dose four times daily.

—Wenthers.

Chronic Urethritis.—

℞ Iodi.....gr. v.
Potass. iod.....gr. xxx.
Ol. oliv.....ʒ ss.
Lanolini.....q.s. ad ʒ i.
M. S. Use to anoint a steel bougie.

—Horwick.

Chancre and Chancroid.—Wash with a camphorated solution of carbolic acid, and apply a moist dressing made with picric acid in saturated solution.—Hawthorn.

Chronic Rheumatism.—The "Chelsea pensioner," which has had an excellent reputation in many quarters, contains:

℞ Rhubarb.....ʒ ij.
Guaiac.....ʒ i.
Bitartrate of potash,
Washed sulphur.....āā ʒ i.
Nutmeg.....No. i.
Honey.....O i.
Dose: A tablespoonful night and morning.

Exophthalmic Goitre.—Hyoscine hydrobrom. gr. $\frac{1}{800}$ and picrotoxin gr. $\frac{1}{20}$–$\frac{1}{10}$ given over a protracted period have had good results.—Herrick.

Oxaluria with anæmia and nervous atony:

℞ Acid. hydrochl. dil.....ʒ ss.
Tinct. ferri chl.....ʒ i.
Syr. simp.....ʒ iiss.
Aquæ.....ʒ iij.
M. S. Tablespoonful three times a day through a glass tube.

—Hazard.

Ozæna.—

℞ Aluminis aceto-tartratis (ten-per-cent. sol.).....ʒ iv.
S. Teaspoonful in a pint of tepid water as a douche several times daily to remove secretions, etc.

Then spray with:

℞ Ext. hydrastis fld.....ʒ i.
Aquæ.....O i.

—Bartholow.

Orchitis.—

℞ Tinct. pulsatillæ.....gtt. xxiv.–xlviij.
Syr. zingiberis.....ʒ i.
Aquæ.....q.s. ad ʒ iij.
M. S. Teaspoonful every hour or two.

—Sturgis.

Strap the testicle and give three times a day:

℞ Tinct. aconiti.....♏ i.
Morph. sulphat.....gr. $\frac{1}{20}$
Antimonii et potass. tart.....gr. $\frac{1}{12}$
Magnesiæ sulphat.....gr. xi.

—*Phila. Hosp. Form.*

Remedy for dyspepsia and constipation:

℞ Fluid ext. of cascara sagrada,
Fluid ext. of rhubarb.....āā ʒ iss.
Fluid ext. of wahoo,
Fluid ext. of juglans.....āā ʒ vi.
Glycerin.....q.s. ad ʒ viij.
M. S. Half a teaspoonful in half a glass of sweetened water after each meal.

—R. C. Kenner, *Med. Summary*, July.

Nervous Dyspepsia.—Medical treatment as in neurasthenia. Weir-Mitchell rest cure. Complete change in habits. Substitution of out-of-door for a sedentary life.—Boardman Reed.

Passiflora Incarnata in dose of five drops of the tincture made from the wild plant gives better results than hyoscyamus, belladonna, or conium in the nervous phenomena of whooping-cough.—Carties.

Neurasthenia.—

℞ Zinci bromidi,
Zinci valerianatis,
Zinci oxidi.....āā gr. xv.
Rosæ conserv.....q.s.
M. ft. pil. No. xx. S. One before breakfast, dinner, and bedtime.

Facial Neuralgia.—

℞ Butyl chloral-hydrat.,
Spir. vini rect.....āā ʒ iiss.
Glycerini.....ʒ v.
Aquæ.....q.s. ad ʒ ij.
M. S. Teaspoonful once or twice daily.

—*Med. Times and Hosp. Gaz.*, June 30th.

Catarrhal Conjunctivitis.—

℞ Zinci sulphat.,
Morph. sulphat.....āā gr. ½
Aquæ destill.....ʒ i.
M. S. Apply five drops to the eye every two hours.

Epsom Salts made palatable:

℞ Magnes. sulphat.....ʒ ss.
Ac. sulph. dil.....♏ ij.
Syr. limonis.....ʒ iss.
Aquæ.....q.s. ad ʒ ij.
Take at dose.

Aphonia Nervosa.—Draw in a deep, easy breath, and on expiration make the attempt to produce a clear note. If successful proceed to other sounds, vowels, syllables, and words of two syllables. A few minutes' practice may result in distinct talking.—Oliver.

Camphorated Oil in one-half drachm to two-drachm dose of a 1 : 10 solution for an adult is the best cardiac tonic and antispasmodic.—Vaillant.

To Cool Water when ice cannot be obtained, wrap the pitcher in cheese-cloth previously impregnated with ammonium nitrate and dried. Moisten slightly at time of use, dry, and use again.

Vaginitis.—

℞ Aluminis,
Sod. biborat ..... āā 30
Quin. sulph 1
Ol. thymi,
Ac. carbol ..... āā gtt. xxx.
Glycerini 200
M. S. Add a soupspoonful to a quart of hot water. Inject two or three times a day.

—Janowsky.

Dysentery.—

℞ Sodii sulphat 30
Aquæ destil 90
M. S. A soupspoonful three times a day.

—Buchanan, *Fortschr. der Med.*, No. 16, 1900.

Supra-Orbital Neuralgia.—

℞ Ergotæ 1
Quininæ mur 2
Ferri sulphat 5
Ext. gentian ..... q. s.
Ut ft. pil. No. c. S. Two pills three times a day.

—Peters.

Painless Mercurial Injections.—

℞ Ol. olivæ sterilizat 100.00
Hydrargyri biniodidi 0.50
Guaiacol (synthetic.) pur 2.00
Inject slowly 2 gm. into the buttock daily or every second day.

—*Bull. Pharm. Sud-Est.*

Sweating in Phthisis.—

℞ Tellurate of sodium 0.10-0.20
Alcohol 50
M. S. A teaspoonful morning and night.

—*Journ. des Praticiens.*

Tannin precipitating gelatin, it is suggested to make use of gelose in preparing capsules or suppositories containing this drug:

℞ Gelose 3
Aquæ,
Glycerin ..... āā 50
Tannin 10

Dissolve the gelose in a water-bath in a mixture of the glycerin and water. Add the tannin, and when it is dissolved poured into moulds.—*Journal des Praticiens.*

Odontalgia.—

℞ Phenol,
Menthol,
Hydrochlorate of cocaine,
Chloral,
Guaiacol ..... āā 2 gm.
Triturate in a mortar.

Chronic Coryza.—

℞ Sod. bicarb.,
Sod. biborat.,
Sod. chlorat ..... āā 0.40 gm.
Sacch. alb ..... 1.00 "

Dissolve in tepid water, pour into the hand, and snuff up forcibly so that the solution passes into the pharynx, or inject into the nostrils.—Morell-Mackenzie.

Generalized Eczema.—

℞ Liq. aluminii acetat ..... 10.00 gm.
Sod. biborat ..... 3.50 "
Ac. salicyl ..... 30 cgm.
Aquæ destillat ..... 170.00 gm.
Glycerini ..... 30.00 "
M. S. Apply as a lotion.

For Amenorrhœa when functional and slight, give half a grain of thyroid extract at bedtime.—Glynn.

Smoker's Heart.—

℞ Adonidin 0.005
Ammon. carb 0.1
Camphoræ 0.03
M. ft. chart. No. xxx. S. One three times a day.

—Stern.

Hæmoptysis.—

℞ Tinct. iodi ..... ℥ i.
Pulv. camphoræ,
Ol. picis (essent.) ..... āā ℥ iiss.
Spt. æth. comp ..... ℥ ss.
M. S. Use for inhalation (five to twenty at a time). Repeat every two to four hours.

—Chartier.

Uterine Fibromata.—

℞ Ergotin ..... 2 gm.
Chloral hydrat ..... 1 "
Aquæ ..... 260 "
Inject twelve drops every day for several months.

—Simpson.

Gastropathies of Cardiac Origin.—

℞ Digitalin (crystal.) ..... 1 gm.
Glycerini ..... 333 c.c.
Aq. destil ..... 147 c.c.
Spt. vini rect. (95 per cent.) ..... q. s. ad 1 litre.
M. S. Ten to fifteen drops for four or five days.

—Carrière, *Gaz. des Hôp.*, June 16th.

Pruritus.—

℞ Plumbi acetat ..... 1 gm.
Acid. hydrocyanici dil ..... 5 "
Spt. vini rect ..... 15 "
Aq. destil ..... 250 "
M. S. Apply as required.

—A. Thompson.

Delirium Tremens.—

℞ Antipyrin ..... 4 gm.
Potass. brom ..... 6 "
Syr. chloral (Fr. cod.) ..... 30 "
Aquæ ..... 125 "
M. S. Teaspoonful every hour until hypnotic effect is produced.

—Villard, *Gaz. des Hôp.*, June 12th.

Scabies.—

℞ Staphysagriæ pulv ..... 300 gm.
Adipis (melted for twenty-four hours at a temperature of 100° C.) ..... 500 "
M. S. Apply for four days, each friction being preceded by a bath.

—Bourguignon.

Neuralgia.—Ol. ricini relieves or greatly improves neuralgia, especially that of the fifth nerve.—Ochsner.

Prostatic Enlargement.—Give ammonium chloride in ten-grain doses, three times a day for three months.—*Medical Summary.*

Gonorrhœa.—Avoid all attempts at abortive treatment with strong injections, Janet's washings, etc. When there is violent inflammation from the first, a one-per-cent. solution of thallin is used as an injection. When the inflammation is slight, nitrate of silver 1 : 10,000 to 1 : 4,000, or permanganate solution.—Casper.

Croupous Pneumonia.—I have found hot poultices more agreeable than cold. I would resort to venesection when there is an overloaded right heart with threatening symptoms. Digitalis is reserved for an irregular and flagging heart; codeine in small doses for the relief of pain and delirium; strychnine in increasing doses and alcohol for enfeebled heart action; calomel and saline for constipation or sluggish portal circulation; oxygen gas is commenced at the first sign of cyanosis and in quantity sufficient to relieve; and last, but by all means first, the absolute recumbent posture until resolution is established.—W. O. Bridges.

Clinical Department.

THREE CASES OF SPECIFIC BASAL MENINGITIS, WITH SPECIAL REFERENCE TO EYE-SYMPTOMS.

By J HERBERT CLAIBORNE, M.D.,

NEW YORK.

CASE I.—A. M——, widow, age thirty-nine years, presented herself at the Vanderbilt Clinic, department of nervous diseases, May 10, 1897. She had married thirteen years previously; her husband had been dead six years, she had never been pregnant. At the time of her first call she had a few enlarged cervical glands, and there was a mucous (?) patch on the left side of her tongue. Four years before she had had paralysis of the right abducens, and recovered after three months of specific treatment. At the same time that she had paralysis of the right abducens she had also paresis of the right arm and leg for three or four weeks, and her mouth was drawn down to the right. Five weeks before she was first seen by me she had had pain on the nasal side of the left orbit which ran up to the vertex and down the side of the face. The lid then drooped and the eye became motionless. For several weeks preceding this occurrence she had had occasional pains with temporary drooping of the left eyelid. She felt dizzy, her legs were weak, and her calves felt numb. The gait was normal, and no Romberg symptom was present. The right knee jerk was weak, the left normal. There was prominence of the left eyeball, with anæsthesia of both corneæ and scleroticæ but not of the face.

Diagnosis: ophthalmoplegia sinistra specifica, retrobulbar exudate.

These notes were transcribed from the records of nervous diseases in the Vanderbilt Clinic. I saw the patient for the first time several weeks after her first visit to the clinic. At that time she had a slight drooping of the left lid, no apparent muscular palsy, and normal pupil and accommodations. The cornea and sclera were anæsthetic, and below the centre of the cornea was an ulcer about one-eighth of an inch in length and one-sixteenth of an inch in vertical diameter. I diagnosed ulcer and paralytic keratitis, and, in view of the preceding history, located the lesion in the orbit toward the apex. I considered it an exudate, specific in origin, probably arising from the structures around the apex.

She was treated for more than a year with antispecific remedies and local applications for the ulcer. I made the following notes: Status, eighteen months after her first visit to me, left lid slightly drooping; moderate anæsthesia of cornea, infiltration of lower third of cornea, covered entirely with blood-vessels; field of vision normal, except for the blurring due to the infiltration; no fundus lesion, $V = \frac{20}{30} +$.

This patient came under my observation on account of the ulceration of the cornea. The characteristic location of the ulcer caused me to test the sensibility of the cornea, when the diagnosis of neuro-paralytic keratitis was immediately made. She presented no symptom of paralysis except a drooping of the upper lid.

Eighteen months after her first visit to me there remained partial anæsthesia and infiltration of the cornea over the site of the old ulcer.

It will be observed that there is a singular association of lesions in this case: paralysis of right abducens, right arm and leg, left facial palsy, left ophthalmoplegia complete, followed several years afterward by complete corneal anæsthesia of the left eye. The paralysis of the right abducens associated with the paralysis of the right arm and leg would imply a basal lesion, disseminate in character, and below the pons. There was probably a simultaneous lesion on the left side at the base to account for the left facial palsy and left ophthalmoplegia. If the left facial palsy is to be accounted for by a high lesion on the right side, there should at least have been left hemiplegia. The hemiplegia, however, was on the right side. These facts, coupled with the corneal complication, lead one to the conclusion that the lesion was basal, probably meningeal, and certainly disseminate and multiple The subsequent slight levator palsy on the left side is corroborative of this view.

CASE II.—Mrs. K——, a delicately built young woman aged twenty-four years, consulted me on December 22, 1899, for loss of sight in the left eye. During the preceding summer she had suffered considerably from dizziness, which she had attributed to constipation that was chronic and obstinate. Six weeks before I saw her, her right arm and leg became suddenly numb and partially paralyzed. Five days before she came to me, she noticed her left eyelids were drawn together, and she could not see well with that eye. The left side of her face was drawn up. Her speech and memory were good. The left palpebral fissure was smaller than the right, there was slight convergence of the eye with diminished movement outward. There was partial tactile anæsthesia of the right upper lid; otherwise the sensibility of the two sides of the face was equal. The tongue, on being thrust out, was inclined to the right, the grip of the right hand was distinctly weaker than that of the left, the knee jerks were excessive. She said her right leg was still somewhat numb, and the skin of the forearm of that side was found also to be numb to the prick of a pin. There was slight Romberg symptom, but no foot clonus. She occasionally still had some difficulty in walking.

The vision of the left eye was $\frac{20}{200}$, the top letter disappearing and reappearing alternately, exhibiting the scotoma centrale fugax. The field was nearly normal in extent, was generally hazy, but apparently was slightly constricted above and to the outer side. The patient was so nervous that it was decided not to take the field with the perimeter. Ordered potassium iodide gr. x. t.i.d., increasing gr. v. daily.

December 25th: The facial paralysis was much worse, sensation in arm and leg was better, grip the same, facial anæsthesia better, scotoma fugax less frequent, $V = \frac{20}{200}$.

December 29th: $V = \frac{20}{70}$; no central scotoma, optic disc slightly congested, and edges fuzzy above and to the outer side; facial paralysis still worse, left eye now nearly closed; squint the same, right grip a little better; knee jerks the same; field about normal, voice husky from potassium iodide; iodide headache, anæsthesia in arms and legs gone.

January 2, 1900: Facial palsy better, left eye more open; field normal, $V = \frac{20}{30}$; grip not quite equal to left hand; tongue straight.

January 7th: $V = \frac{20}{30}$; grip improved, face much better.

January 14th: Almost recovered; $V = \frac{20}{30}$, facial palsy gone. She suffers from headache, examination of refraction shows: R.E. $V = \frac{20}{15}$ w. + .50 D. c. ax. 90°; L.E. $V = \frac{20}{15}$ w. + .25 D. c. ax. 90°.

She went to the theatre one night and had a blind spell; on that account and on account of the persistent headache, the refractive examination was made. She was then sent away on a trip to the South. The potassium iodide had been given in as large doses as gr. lxv.–lxx. t.i.d. This was finally reduced to gr. xx. t.i.d. Subsequently she was put upon the mixed treatment and was advised to continue this till further orders. Her family physician, during the treatment with potassium iodide, was using maltine and cascara

for the constipation. The galvanic current was used regularly over the area of distribution of the palsied seventh nerve.

This case seems simpler and clearer than the first. A young married woman develops right hemiplegia, and hemianæsthesia of a mild type. This becomes better without treatment. Six weeks afterward there is right facial paralysis with very slight palsy of the left external rectus. The tongue, on being extruded, pointed distinctly to the right. The vision in the left eye was lowered to $\frac{20}{200}$ with a fleeting central scotoma. When I saw her there was mild right hemiplegia and anæsthesia. The lesion on the right side must have been low enough down to catch the motor and sensory tracts below the pons; at the same time the hypoglossal and the seventh nerve were attacked. Another lesion on the left side must have lain between the chiasm and the apex of the orbit, jugulating the fibres of the left optic nerve and slightly interfering with the conduction of the left abducens. It would be possible to explain the right hemiplegia and right facial palsy on the ground of a lesion above the pons on the left side, but the fact that there was at the same time a right hypoglossal palsy would necessitate the coexistence of a right-sided lesion. It is far more reasonable to assume a right-sided low basal lesion for the palsies of the right side.

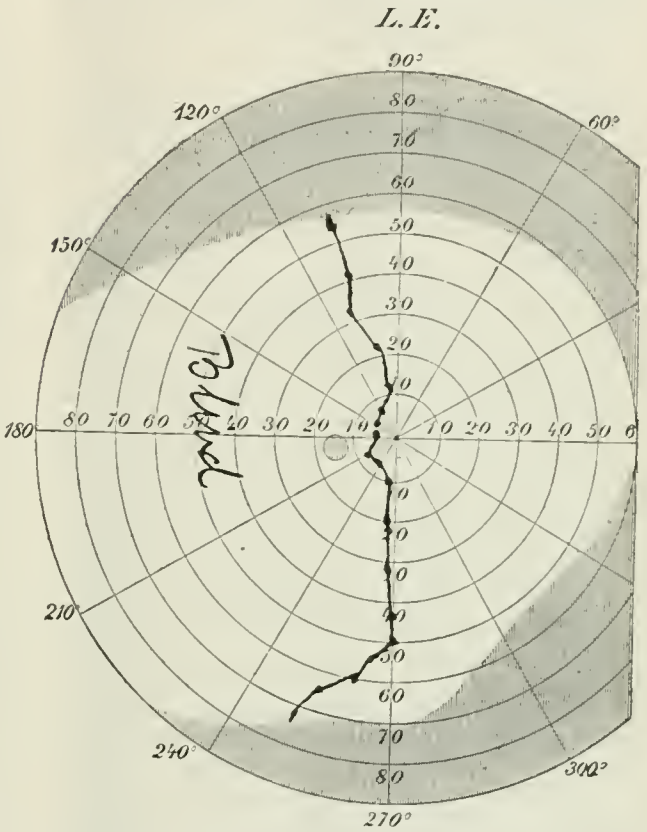
The facts of the case lead one to the diagnosis of a basal, disseminate, multiple meningeal lesion.

Case III.—B. M——, aged twenty-four years, a mulatto woman, states that two and one-half years ago, she awoke one morning to find that she could not see with her right eye. At 1:40 P.M. of the same day she was taken to the hospital. The left eye remained good until 6 P.M., when it became totally blind like the right eye. Immediately after this she became unconscious and remained so four weeks. She stated that when she regained consciousness the left side of her face was paralyzed, was numb, and that her tongue, on being thrust out, went to the left. She had difficulty in eating and kept biting the left side of her tongue. Both eyes bulged, and "shells came off her upper and lower teeth." The left ear was quite deaf and there was much roaring in it. She found her right eye still totally blind; she could see with her left, but it was weak; she had to bring objects close to see them. Her sense of smell was entirely abolished. In two months the sight of her right eye returned imperfectly. The sight of the left eye was good.

I saw her first in October, 1899; she said that during the summer of that year the sight of the right eye commenced to fail again and became totally lost. Her status at the time I saw her was as follows: R. E., totally blind, the pupil was extremely dilated from atropine, cornea and sclera were completely anæsthetic; on the lower third of the cornea, extending almost to the sclero-corneal margin, was an elliptical ulcer; the optic nerve was dead white; the arteries were very small; the veins were moderate in size; there was no other lesion in the fundus. There were some lacrymation and conjunctivitis. L.E. V = $\frac{20}{30}$, but the field was distinctly hemianopic on the left side as shown by the chart. The field was somewhat constricted below and was totally blind to the temporal side of demarcation. The good vision, viz., $\frac{20}{30}$, is explained by the fact that the macula fibres were not involved in the lesion.

In this case a mulatto woman wakes to find herself blind in her right eye; at 6 P.M. of the same day she becomes blind in the left, then falls unconscious and remains so for four weeks. On regaining consciousness, she has left facial paralysis, left hypoglossal paralysis, deafness and tinnitus in the left ear; right eye still blind and left eye's sight still impaired. Sense of smell destroyed; in two weeks sight in the right eye returned imperfectly, while the sight of the left eye was good. At the end of two and one-half years from the original attack she consulted me on account of total blindness of the right eye and an ulcer on the cornea of the right eye. The right optic nerve was totally atrophic and the left nerve also gave the appearance of optic atrophy, while the field, as shown by the accompanying chart, was almost classically hemianopic. The blindness was temporal, and the V = $\frac{20}{30}$.

It is difficult to conceive of a more characteristic picture of basal meningitis and its final results. First, blindness in the right eye, then in the left; subsequently involvement of the left facial, left hypoglos-



sal, left auditory, the olfactory apparently on both sides, total atrophy of the right optic nerve, and partial atrophy of the left. The hemianopic lesion is particularly interesting. The left-sided temporal hemianopsia indicates a lesion in the right optic tract, and if there had not been a complete involvement of all the fibres destined for the right eye, there would assuredly have been left-sided homonymous hemianopsia. Since the right eye became totally blind, the matter resolved itself into left-sided temporal hemianopsia.

The complete atrophy of the right optic nerve was doubtless due to the exudate passing beyond the tract and chiasm, and choking the nerve at its entrance into the optic foramen. That perfect vision remained in the left eye was due to the fact that the line of the dead nerve fibres stopped short of the macula—the usual fact in such cases.

The neuro-paralytic keratitis in this case, as in Case I., indicated that the fifth-nerve fibres bound for the cornea were involved. They were apparently destroyed in Case III., since the corneal anæsthesia remained after two and one-half years. In Case I., they were not totally destroyed, but their conduction was interfered with, as was shown by the moderate sensibility of the cornea at the time of my observation.

The young woman described in Case II. was a sufferer from chronic constipation. She consulted

a very busy practitioner concerning her constipation and mentioned the numbness and loss of power in her right side. He paid no attention to the symptoms, and apparently attributed them, together with the dizziness, to the constipation. A few days after she mentioned the fact that she could not see with her left eye to a physician whom she met at a social function, and made light of the matter. He observed a slight facial palsy at the same time, and immediately referred her to me. Her rapid recovery under mercury and iodide of potassium proclaim the cause, in all probability, to be specific.

The circumstances surrounding Cases I. and III. make the specific etiology clear. The three cases present an excellent opportunity for the study of the lesions at the base of the brain.

39 West Thirty-sixth Street

HERNIA OF THE OVARY AND TUBE AND THE VERMIFORM APPENDIX.

By F. C. LARIMORE, M.D.,

MOUNT VERNON, OHIO

A left oblique inguinal hernia containing the ovary, tube, and vermiform appendix is certainly of such a rare occurrence as to justify publication. The ovary or the ovary and tube, and on the right side the appendix vermiformis, have been found in a hernial sac, but to find all of these combined in an inguinal hernia on the left side may be unique.

O. A——, aged thirty-five years, consulted me first on October 17, 1899, for a hernia. I found a left oblique inguinal hernia, irregular and doughy, the size of a small orange, and irreducible. The mass could be crowded up, but some portion would still remain outside the external ring. The woman was wearing a truss, and stated that she had had trouble on that side in childhood, and during the past fifteen years the lump had increased in size and was more and more painful. Operation was advised for the radical cure. She entered my private hospital May 31, 1900. I found the lump as above described. It impressed me as being a lipoma, the omentum, or an ovary. On June 1st I operated, chloroform being given by Dr. R. W. Colville. A three-inch incision was made over the inguinal canal one-half inch above Poupart's ligament. The aponeurosis of the external oblique was divided on a grooved director. The hernial sac was dissected up with the finger. The sac was opened and found to contain the ovary and tube. The ovary was located outside of the external ring and firmly attached. The other end of the tube ended in a blunt extremity. The entire tube was as thick as the little finger and four inches long. The ovarian artery was as large as the radial, with seven other arterial trunks in the sac wall, three in one group and four in the other. The appendix vermiformis was found in the neck of the sac with firm adhesions. This was ligated off with catgut, and the sac was dissected up completely with ovary and tube transfixed, the two tubes were ligated separately, and then combined. This method of treating the sac differed from my usual custom in the use of a larger-sized catgut, and in the firmer tying. This departure put my mind at rest when I discovered the very unusual arterial blood supply. The internal oblique and conjoined tendon were united to Poupart's ligament with five interrupted sutures, inserted with a full-curve Hagedorn needle. The aponeurosis of the external oblique was closed with a continuous suture. These sutures were of kangaroo tendon, kept in carbolized oil, and at the time of operation placed in a 1 : 1,000 sublimate solution in a tumbler, and used directly from the same. The skin incision was closed with a subcuticular suture of catgut, 0 size.

There was no vomiting from the anæsthetic. The highest pulse was 80; the temperature 99.2° F. on the second day. Since then the pulse has been from 68 to 72, and the temperature 98.6° F. The wound was inspected on the eighth day, and primary union was found to be complete.

This method would generally be styled Bassini's, but I wish to render tribute to whom tribute is due, and would call it the American operation as first devised by Dr. Henry O. Marcy.

A CASE OF HODGKIN'S DISEASE.

By J. N. STUDY, M.D.,

CAMBRIDGE CITY, IND.

This curious affection of the lymphatic glands and tissues, which has been known by a plurality of names, was well described by Hodgkin, a pathologist to Guy's Hospital, in 1832. Some of the older writers had given it the name of lymphatic cancer. It has been classed in the same category as cancer, the malignant nature of which it closely resembles, but pathology teaches us that it bears no relationship to either cancer or tuberculosis, and is treated of under the title of disease of the blood and ductless glands. The affection is simply a hyperplasia of the lymphatic glands. There is generally marked anæmia, and there may be an increase of the white blood corpuscles, and the character of the blood become that of a lymphatic leukæmia. The affection has a predilection for young adults between twenty and thirty years of age; next for persons between fifty and sixty years of age, and children are not infrequently subjects of this disease. Three-fourths of the recorded cases are said to have been in male subjects. As to the cause and origin of the disease we know nothing, and the affection sooner or later usually terminates in death, and the physician stands practically powerless to aid the sufferer. It is believed that the following case presents some features worthy of being recorded:

Ivan L——, male, aged six years and nine months, American, an intelligent child, well developed, and in rugged health. The father is living and there is an excellent family history; the mother is living, but in delicate health. One sister died from tuberculosis. The child was observed to have some difficulty in swallowing some varieties of food on January 15th of the present year, and at the same time a small lump, barely noticeable, was seen immediately below and posterior to the right ear; it was not painful and was freely movable. Both tonsils were much enlarged, and, to all appearance, the disease had begun in the tonsils. The child soon showed marked anæmia accompanied by a rapid pulse and occasional increase of temperature in afternoons of one or two degrees. These symptoms all persisted throughout the illness of the child. The tonsillar enlargement, which affected both tonsils, increased until the vault of the pharynx was well filled, the anterior pillars of the fauces being pushed forward and the uvula upward and forward. A small fissure only could be seen between the tonsils, but liquids and semisolid articles of diet were swallowed surprisingly well. The tonsils bled easily when a tongue depressor was forcibly drawn over their surfaces. Air was admitted almost wholly through the posterior nares, and sleeping was often interrupted by the most distressing and at times alarming symptoms. Upon the right side of the neck all of the cervical glands rapidly became involved, at first each was movable and of an elastic feel, but finally they coalesced, making an enormous mass extending upon the right side from the mastoid process down to and obscuring the clavicle.

The enlargement was sufficient to cause the head to be considerably turned to the left. The vertical diameter of this tumor measured eight inches; its transverse diameter seven inches. There was a glandular enlargement below and behind the left ear as large as a small lemon, freely movable, and elastic to the touch. The skin over these tumors had a healthy appearance. There was a glandular enlargement in the right axilla of considerable size, and the glands in either groin were perceptibly enlarged and movable. At no time was any pain complained of. The voice was of a nasal character and somewhat difficult to understand. At times marked drowsiness was present.

Physical examination at no time revealed any disease of the lungs. On April 26th, at 9:30 P.M., the child was sleeping, when his breathing became very bad; he awoke, and in an effort to get more air by going to the open door, as he had done before, he strangled and died in his mother's arms of asphyxia.

Eighteen hours after death the large mass of glandular tissue was dissected out. It was a mass extending down and adhering to the deep muscles and fasciæ. The large vessels and nerves were deeply incorporated into the glandular mass, which weighed one pound. This mass of glands on section was of a dark gray color, with numerous white fatty masses as large as peas scattered through it. When scraped a milky substance exuded from the surface. There were no caseous glands nor was there any suppuration.

A CASE OF PERNICIOUS ANÆMIA—HUNTER'S TREATMENT—AUTOPSY.[1]

By CHARLES E. NAMMACK, M.D.,

NEW YORK.

Patrick L——, forty-eight years old, steamship fireman, was admitted to Bellevue Hospital May 3, 1900. He stated that for four months past he had suffered from occasional attacks of vomiting, with gradually increasing weakness and loss of flesh and marked yellowness of the skin. Prior to this illness, he had not been confined to bed for thirty years. He is in the habit of sailing to southern ports. He has never drunk while on board ship, but would drink moderately while in port. He has never acquired venereal disease, but admits having taken many chances to do so.

On admission the pulse was 100, respiration 22, and rectal temperature 99.8° F. The patient was poorly nourished. The skin was a lemon-yellow color without variations on the cheeks and forehead. The subcutaneous layer of fat was not well preserved. There was no mucous or subcutaneous hemorrhage. The mucous membranes and nails were strikingly white, even by contrast with cases of cancer and scurvy present in the wards. The tongue was pale, smooth, and shiny. The skin had a soft velvety feel which contrasted well with the dry, harsh skins of neighboring cases of secondary anæmia. The gums were not fungoid and did not bleed on pressure. The teeth showed the appearances common to neglect, but were not carious. The man's expression was listless, and his breath was offensive. The pulse was small and regular. Arterial tension was moderate. Heart impulse and sounds were weak. There was a basic systolic murmur transmitted into the neck. No water-hammer pulse was discovered. Capillary pulsation was absent. There were neither symptoms nor physical signs of involvement of the peripheral nerves, spinal cord, or brain. Uranalysis was negative. An average of several blood counts showed: red cells, 560,000; white cells, 2,900; hæmoglobin, twenty per cent. (Fleischl). Study of the cells, as hereinafter mentioned, determined the clinical diagnosis of pernicious anæmia.

This patient presented a profound anæmia without adequate known cause, characterized by extreme diminution in the red cells and other changes in the blood, and by absence of marked emaciation. The blood changes were those characteristic of pernicious anæmia, namely: (1) Reduction of the red cells to less than 1,000,000; (2) absence of leucocytosis; (3) presence of nucleated red cells, of which a majority were megaloblasts; (4) presence of polychromatophilic red corpuscles; (5) increase in the average diameter of the red cells; (6) diminished absolute hæmoglobin but relative individual corpuscular richness in hæmoglobin. Before accepting this clinical diagnosis, gastric carcinoma, which closely counterfeits pernicious anæmia, was excluded by the absence of progressive emaciation; the presence of lemon-yellow instead of muddy skin; the absence of enlargement of the supraclavicular and inguinal glands; the absence of palpable signs of stomach affection; the negative results of chemical examination of the stomach contents after the Boas test meal; the absence of leucocytosis; and the presence of the essential diagnostic criterion, to wit, nucleated red cells, of which a minority were normoblasts and a majority megaloblasts.

Now that hæmatology plays so important a part in clinical medicine, cases of pernicious anæmia are not so rarely found. Cabot's list of cases has increased from sixty-six in 1897 to one hundred and ten to May 1, 1900. Its prognosis, however, still is said to be almost invariably fatal. Into this gloomy picture a ray of hope has recently been projected by the studies of Hunter.[1] According to Hunter, the disease is a toxæmia, resulting from special infection of the digestive tract, and treatment, to be successful, must be based upon antisepsis of that tract and the introduction of some serum which will counteract the infection. In the absence of more exact knowledge of any specific serum, W. Elder[2] reports a case treated in accordance with Hunter's idea by mouth washes, salol with salicylate of bismuth, and injections of antistreptococcic serum. The result was truly remarkable, the blood count becoming practically normal in forty-five days. But whether this result was due to the treatment, or was one of those spontaneous waves of improvement which are so marked a feature of the disease,[3] remains to be proved.

After this case had been reported as above, the patient failed rapidly, and died of exhaustion June 12th. Autopsy was made by Dr. Harlow Brooks, sixty hours after death. Dr. Brooks' report follows: The body is that of a well-developed man and moderately well nourished. The skin and mucous membranes are much blanched. The pupils are slightly dilated and the scleræ jaundiced. A depressed scar is seen over the right inginal canal. The musculature is fairly abundant and of light color. Axillary lymph nodes are enlarged. There are occasional bands of pleuritic adhesions in both pleural cavities, especially in the right. A few pleuro-pericardial adhesions exist. The pericardial sac holds about 50 c.c. of bright yellow fluid containing floccules of fibrin. The epicardium shows numerous old patches of epicarditis. The heart is enlarged and its walls are collapsed. The heart muscle is very soft and light in color. The valves are universally thickened. There is decided fatty infiltration. The coronary arteries are large and show slight arteriosclerosis, which is also noticed in

[1] Patient presented before the Section on Medicine, New York Academy of Medicine, May 15, 1900.

[1] Lancet, January 27, February 3, and February 10, 1900.

[2] Lancet, April 28, 1900.

[3] Shattuck and Cabot: "American System of Practical Medicine," vol. ii., p. 676.

the arch of the aorta. The heart weighs sixteen ounces. The tongue is moderately coated and a few small hemorrhages are seen near its posterior surface. The thyroid gland is small, light yellow in color. The peribronchial lymph nodes are enlarged and anthracotic. The pharynx and œsophagus are normal, except for marked anæmia. The lungs are extremely œdematous, the œdema being of a characteristic, greenish color. Marked anthracosis exists in the right upper lobe with extensive development of fibrosis.

The gall bladder shows, about its fundus, a considerable extravasation of bile. The liver is adherent to the diaphragm in many places, is moderately enlarged, and there is marked portal congestion. The hepatic lobules are marked out in light yellow from bile staining, and there is quite marked interstitial overgrowth. The liver weighs four pounds. The gall bladder contains 20 c.c. of mucoid, greenish bile.

The spleen is enlarged, light purple in color, with markings distinct, consistency soft, weight twelve ounces.

The lower portion of the ileum is attached to the sheath of the right psoas muscle. The mesentery is fairly rich in bright yellow fat, and the mesenteric nodes are enlarged. The small intestine has an anæmic mucous membrane, but is otherwise normal. The stomach is small, mucous membrane anæmic, rugæ are absent, with no ulceration, no new growth. The vermiform appendix is 6 cm. long, 2 cm. thick, and its tip is attached and adherent to the colon about 6 cm. above the caput. The wall of the appendix is enormously thickened and its lumen is obstructed by an overgrowth of connective tissue representing long-standing self-healed appendicitis, which probably ruptured into the colon. The pancreas is large, color light, tissue firm. The suprarenal bodies are small, with cortices stained light yellow, and the structure is apparently normal.

The kidneys are large, weight fifteen ounces, markings distinct and regular, the cortex is very thin, connective tissue markedly increased, consistence very firm. The upper portion of the left kidney shows anæmic infarction.

The skull cap is symmetrical and well formed, and shows a small amount of cancellous bone. The dura mater is anæmic, and incision liberates a considerable amount of deep-yellow serum. The brain is small, well formed, the convolutions are large and symmetrical, sulci deep, the pia is quite œdematous, the ventricles are normal. The cause of death is chronic idiopathic anæmia.

42 East Twenty-ninth Street.

PROTRACTED GESTATION IN AN OLD PRIMIPARA.

By J. BARAN, M.D.,

new york.

Mrs. L. W—— was born in September, 1854. She menstruated first at the age of twelve years, and very regularly thereafter every twenty-eight days. She was married in 1892, being then thirty-eight years old. She became pregnant about two years later, but miscarried at about two and one-half months. On June 11, 1899, she menstruated for the last time, and had symptoms of pregnancy at least one week before July 9th, at which time her menses should have reappeared. But, as expected, there was no show. She felt quickening on November 1st. According to calculation she should have been delivered about March 18th, but no sign of beginning labor existed even on April 19th, on which day, fearing the growth of the child to very large proportions, although the pelvis appeared ample, I decided to force labor and gave the patient a large dose of castor oil. I cannot believe that it was a coincidence, but after the oil acted labor pains developed. The first stage of labor lasted sixty hours, the second and third stages only a short time. The woman was delivered on April 22d, three hundred and fifteen days from the beginning of the last menstruation. How much longer she might have carried is, of course, only conjectural. The baby was large, bony, not fat; it had considerably elongated nails, but no unusual growth of hair. Dr. Lusk says: "Gestation protracted beyond the two hundred and eighty-fifth day is certainly of very rare occurrence." My patient went at least ten days over that time. Her age, almost forty-six years, is certainly also very unusual for a primipara.

A CASE OF TETANUS TREATED WITH ANTITOXIN.

By GEORGE M. CONVERSE, M.D.,

new york.

Martin T——, thirty-four year old, single, a gardener in Long Island, entered St. Francis Hospital, New York, on March 6, 1899, suffering from frozen fingers, pain all over the body, and inability to open the mouth. He had always been healthy, temperate, and denied any venereal history. The fingers of his right hand were frozen during the blizzard on February 9, 1899, and were dressed at a dispensary. He contined with his work. On the day of entrance, the last phalanges of the ring and little fingers were gangrenous and painful; the patient's face was flushed and covered with great beads of perspiration; the forehead was wrinkled and the eyelids were drooping, the general expression being that of the "risus sardonicus." He couid not separate the teeth more than 1 cm., at the same time the lower jaw was drawn backward so that the lower incisors were nearly 2 cm. posterior to the upper incisors. He could move his head from side to side but not antero-posteriorly. At intervals varying from fifteen minutes to an hour he had painful contractions in both legs, in the chest which felt as if it were squeezed in a vice, and in the masseters. From the day of entrance the man rapidly became worse; the tonic spasm spread to all the muscles of the back and legs until these were as rigid as those of a cadaver in rigor mortis. At varying intervals, mostly in the afternoon and night, this condition was exasperated by paroxysms of intensely painful clonic spasms. During these and until relieved by chloroform he would shout at the top of his voice. This cry, caused at first by intense pain, became somewhat automatic, so that frequently during the succeeding days, and in the absence of clonic spasms, he would begin to shout at the top of his voice during each expiration. Two days after admission, and while in this condition, the man consented to amputation of the diseased fingers. This was done by the house surgeon, Dr. G. H. Matthews, under general anæsthesia. Then followed a period of sixteen days during which the general rigidity persisted and clonic spasms occurred, with maximum frequency and intensity on the third, fourth, and fifth days, and again on the eighth day, when the pectorals and the muscles of the arms became involved and respiration was difficult for a day; from the eighth to the eighteenth day the symptoms gradually abated in intensity.

At various times, corresponding to maximum injections of antitoxin, the muscles would relax for a few hours so that the patient could bend his knees, lie on his side, and thus obtain a greatly needed rest.

Consciousness was intact most of the time. At the height of this period the patient exhibited a number of times what is called echolalia. On saying to

him "Hallo, Martin!" he would repeat with each expiration, "Hallo, hallo!" etc., during a minute or two.

There was at first constipation, followed later by involuntary evacuation of fæces and urine. The urine remained scanty, high-colored, filled with urates until the fifteenth or sixteenth day, when the perspiration diminished and the urine increased until it reached an amount of two and one-half litres per twenty-four hours.

On the 26th of March, or the twentieth day in the hospital, when the patient was quite well of the tetanus and had only a slight rigidity of the masseters, pain and rigidity began anew, but this time were limited to the right leg. A diagnosis of phlebitis was made, and it was only at the autopsy seventeen days later that it was seen that pyæmia had caused death. The treatment consisted of a few whiffs of chloroform during the paroxysms. Chloral and potassium bromide were also given the first days, but abandoned on account of the effect on the heart, the pulse becoming irregular and feeble.

Tetanus antitoxin was obtained from the bureau of the board of health in vials of 20 c.c., and, with antiseptic precautions, was injected deeply into the arms and thighs: 20 c.c. on the second day, 40 c.c. on the third, 80 c.c. on the fourth, and thereafter for six days, afterward gradually diminishing, to stop on the twelfth day. Altogether 720 c.c. was given.

The notes of the case kept from day to day show that the number of paroxysms of clonic spasms were less after the doses of 80 c.c. of antitoxin had been reached.

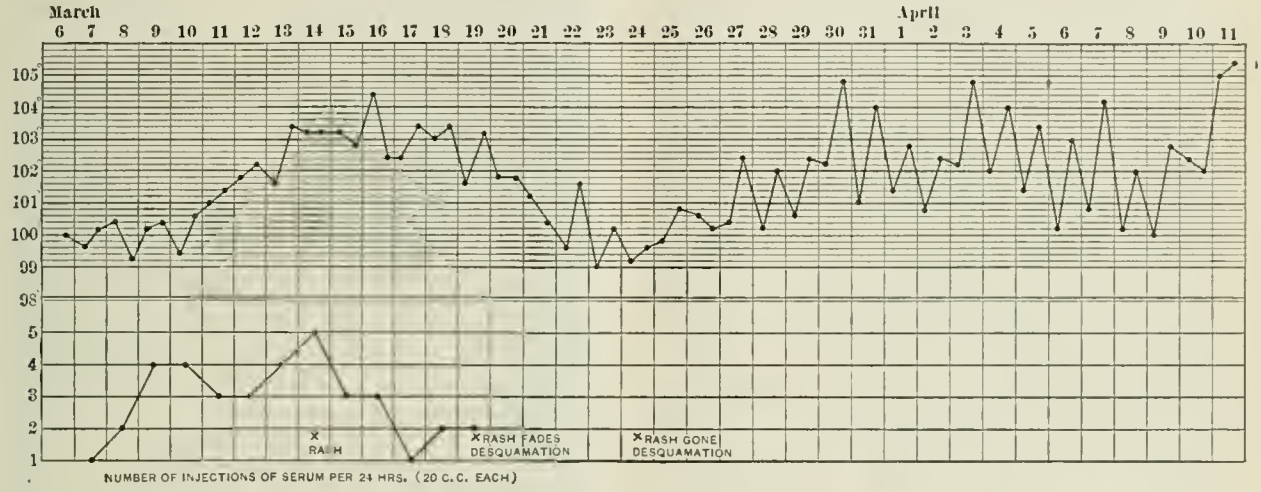
On the evening of March 13th, seven days after the first injection, and when 500 c.c. had been given, an eruption appeared about the points of injection on the arm; this spread rapidly and in twelve hours covered both arms, the back and legs, and the abdomen. At first pink, it became dark red, wine red; confluent on the back and arms; at other points it occurred as profusely scattered, hard papules also of deep red color. Five days later desquamation began, and in ten days the eruption had disappeared completely, having caused no other inconvenience than some itchy sensations.

The diet was milk, and the patient also drank an enormous quantity of water. The patient's death from pyæmia, after his recovery from tetanus, is ascribed to the use of a vial of serum that was not hermetically sealed, and that had been standing on a window-sill for several days during which the temperature rose above the freezing-point.

The amputated fingers were sent to Dr. Larkin at the College of Physicians and Surgeons. He excised small pieces and introduced these under the skin of two small guinea-pigs of 250 gm. in weight. The animals were carefully watched for three weeks, but the results were negative. The autopsy of these was also negative. Microscopical examination of the diseased fingers showed only granulation tissue and necrosis of the phalanges.

In conclusion I would say that this was not an acute case of tetanus; it was a severe subacute form, one in which the patient might have recovered without antitoxin; it is reported, however, because antitoxin was used.

330 West Fifty-seventh Street.



CRYING OF A CHILD IN UTERO.

By M. J. DAVIES, M.D.,
Utica, N. Y.

The history of the following case may be of considerable interest to my fellow-practitioners, especially to those who make a special study of obstetrics. To myself it has been unique, as I have not had such an experience before, and, in so far as I have been able to learn, none of my professional brethren in the city has met with a similar case.

Mrs. A——, aged twenty-four years, became pregnant for the third time about March 20, 1899. There were no exceptional symptoms during the succeeding nine months. At 2 A.M. on December 31, 1899, I was summoned, the message being that pains were very severe and coming on rapidly. Upon arriving at the house I found the patient as stated above, everything indicating a rapid delivery, but upon making an examination there was found a very rigid cervix with a dilatation of the os that would admit the index and middle fingers. Severe contraction continued. At 6 A.M. another examination was made. I found no progress toward dilatation. During the next hour the pains grew less severe and frequent, finally stopping at 7:30 A.M. Nothing more was heard of the case until about 9 P.M., when the same message was sent as before. I arrived at the house about 9:30, and found the patient in good spirits, though suffering intensely. An examination revealed the same conditions as during the morning hours. At 2 A.M. another examination was made. The os was found to be dilated about the size of a fifty-cent piece; the membranes were not ruptured, the presenting part being the head and in the right occipito-posterior position. At 6 A.M., January 1st, the contractions ceased as during the previous morning. The patient passed a very comfortable day. At 7 P.M. I called at the house and found my patient beginning to suffer, contractions being severe, and at intervals of about three minutes. The cervix was more flattened out, with the os slowly dilating. At 9:30 the os was

about three-fourths dilated. The patient began to show signs of weakening. Thinking that perchance if the membranes were ruptured, permitting the liquor amnii to escape, the head would become engaged in the superior strait, and a rapid delivery would be the result, this was done; but to my sorrow this result did not obtain.

As the pulse was showing signs of weakening, I concluded that it was time to interfere by the application of the forceps, the right hand being used to guide the left blade into position, which was easily accomplished, but when an attempt was made to introduce the right blade there were violent movements of the child, which made the sound of crying six or eight times that was heard by the patient, her husband, her mother, and myself. Never having experienced such a thing before, I was very much surprised. On withdrawing the forceps the little one again cried, the sounds being heard as distinctly as before. At the same time the patient exclaimed, "My baby is born, but why did you push it back, doctor?" The husband was sent for an assistant, that an anæsthetic might be administered and the woman delivered.

At the same time that the husband left the house I stepped into an adjoining room. While conversing with a friend of the family, I heard again the crying of the child; the sounds were so loud and distinct that I supposed a spontaneous delivery had taken place. Hastening to the bedside, the babe was still found to be in the uterus. The sounds made by the child the last time were very loud and long, there being at least from ten to fourteen sobs. Upon the arrival of an assistant I concluded that the most rapid method of delivery would be to perform version, having, as before mentioned, attempted to adjust the forceps and failed. As soon as the patient was anæsthetized version was performed, and a male child weighing seven and one-half pounds was delivered. Very slight pulsation was perceptible at the cord. Artificial respiration was performed, when soon the pleasing sound of crying was heard.

The child is now four and one-half months old, and doing nicely. The mother made a rapid convalescence, and within four weeks was doing her own housework.

Why the child cried before birth is a hard and difficult question to answer. Certainly it must have obtained air in some manner. At the time of first crying it is easy to theorize how air was obtained, with three fingers of the right hand in the vagina, and upon attempting to introduce the left blade of the forceps there existed a patent canal up to the os. The child being in the R. O. P. position the air readily reached the face; but without hand or forceps in the vagina it seems almost incredible that air could enter. It might be said that there was sufficient air that entered the first time to suffice for the crying later on.

ANEURISM OF THE ARCH OF THE AORTA.

By HUGHES DAYTON, M.D.,

NEW YORK.

The following case, which was observed at the New York Hospital during the term of service of Dr. A. Brayton Ball, is briefly reported in view of the peculiar physical signs due to interference with the circulatory system, and of the explanation of their etiology which was furnished by the autopsy. Only an imperfect history could be obtained from the patient, Vincenzo P——, an Italian, fifty years old, single, a barber, admitted to New York Hospital April 9, 1900. His family history presented nothing of significance. His past history was negative except malaria thirty years ago lasting three months, and three attacks of gonorrhœa. No history of syphilis or rheumatism could be obtained, and the patient had never suffered from dyspnœa, cough, bloody expectoration, or œdema of the extremities. He did not recall having been subjected to any sudden or protracted strain. He acknowledged the habitual consumption of one or two glasses of wine daily and occasionally a little beer. About two years before admission to the New York Hospital he began to have a persistent and troublesome cough with rather profuse muco-purulent sputum. The attacks of coughing were accompanied by palpitation of the heart and were sometimes followed by vomiting. There were no other gastric symptoms at any time. One year before admission the superficial veins of the abdomen and lower extremities became enlarged, and three months before those of the upper portion of the chest and upper extremities were similarly affected. The cough had continued without improvement, though the sputum had become scanty, and there had been constantly increasing dyspnœa. There had been no thoracic pain at any time, but some in the lumbar region at intervals for about five years. The appetite was fair; the bowels were irregular. The chief complaint was of the cough and oppression in the chest.

Physical examination, April 9, 1900: General appearance—rather poorly nourished, somewhat cyanotic, suffering from dyspnœa which was practically orthopnœa; tongue moist, fissured, heavily coated. The most noticeable feature was the great distention of all the superficial veins, which were also extremely tortuous, and the walls of which were much thickened. An excellent idea of this appearance is furnished by the accompanying illustration from a photograph by Dr. J. B. Solley, Jr. During the paroxysms of coughing the distention of the veins was much more marked, the superficial epigastric being three-eighths to one-half an inch in diameter.

Heart: There was visible pulsation of the whole anterior portion of the chest wall, which showed marked prominence, especially at the second left intercostal space near the sternum, where a mass with distinct expansile pulsation was felt. The apex beat was diffuse. The area of cardiac dulness extended to the right border of the sternum; above, to the third intercostal space. There was also an area of dulness between the clavicles and second ribs, extending to the right as far as the middle of the right clavicle, and to the left to within one inch of the left mammillary line. The aortic and pulmonic second sounds were accentuated. The heart sounds were obscured by violent respiration and coughing. There was no thrill; no murmurs were heard. Tracheal tug was obtained. The pulse was frequent, regular, small in proportion to the intensity of heart action, with good tension.

Lungs: Over the upper portion of the right chest behind breathing and whisper were rather amphoric: over the rest of the right chest posteriorly were sibilant and sonorous breathing and subcrepitant râles. Over the left chest behind down to the angle of the scapula the breathing approached an amphoric character; below the angle, it was diminished and high-pitched.

Abdomen: Slightly distended and tympanitic.

Liver and spleen: Normal.

Extremities: Normal except for cyanosis and dilatation of veins as stated above.

Course of disease: The rectal temperature rose, soon after admission, to 104° F., and subsequently varied between 100° and 102° F.; respirations, 24 to 36; pulse, 80 to 124. Urine: specific gravity 1.031, acid, orange, turbid, no sugar, albumin gm. ¼ to the litre; passed daily twenty-four to thirty-eight ounces; there were a few uric-acid crystals.

Dyspnœa continued severe and cough frequent and

troublesome. The patient slept only in the sitting position. On April 17th there was found from the angle of the left scapula down dulness increasing to flatness toward the base, with nearly absent fremitus, voice and breath sounds.

At 7:15 A.M. on April 18th the patient became cyanosed and covered with cold perspiration, and the pulse was very weak. He died at 7:40 A.M.

Treatment consisted merely in the administration of potassium iodide in doses of gr. xv. three times a day, and the alleviation of cough by appropriate remedies.

Autopsy by Dr. L. A. Conner, assistant pathologist, showed aneurism of ascending and transverse portions

of the arch of the aorta; obliteration of both innominate veins; ulcer of the stomach; secondary pneumonia.

Inspection: Poorly nourished, muscular; slight œdema of ankles; the superficial veins of both sides of the neck, chest, and especially of the abdomen are tortuous and greatly distended, some of them having the diameter of a lead pencil; slight prominence of second intercostal space on either side of sternum. The peritoneum and pericardium are normal. The diaphragm is at the fifth rib on the right side, and at the sixth intercostal space on the left.

Pleuræ: The left pleural cavity contains 600 c.c. of serous fluid.

The heart is displaced somewhat downward and to the left; the valves are competent; the muscle is light-colored and rather soft.

Aorta: The entire anterior mediastinum is occupied by an aneurismal mass which is firmly adherent to, and has partially eroded, the manubrium sterni. The sac also projects through the second intercostal space on either side of the sternum. For a distance of 3 cm. above the aortic valves the aorta has a diameter of about 3 cm.; beyond this it suddenly widens into a great sac 12 to 15 cm. in diameter. This sac is in some places lined with laminated clot, 1 to 2 cm. thick, and in other places is quite free from clot. The innominate artery is given off from the sac at about the middle of its upper surface; the left carotid artery, from its left wall. Immediately beyond this the aorta suddenly assumes its normal calibre, and just at this point the left subclavian is given off. The trachea and bronchi are apparently not greatly compressed, although firmly adherent to the aneurism.

Superior vena cava: This vessel runs up along the right wall of the aneurism, gradually diminishing in calibre until it becomes a small vein which communicates in a tortuous way with the right subclavian vein. Both innominate veins traced from above are lost and obliterated in the aneurismal wall.

Azygos veins: Both of these are much dilated and engorged, as are also the œsophageal veins.

Lungs: The lower lobe of the left lung is completely consolidated, of light reddish color, rather tough consistence, and shows scattered throughout many small yellowish or whitish areas which may be foci of suppuration. A similar condition exists in the middle lobe of the right lung. The bronchi contain much muco-purulent secretion. Microscopic examination shows the consolidated area to be a somewhat unusual type of broncho-pneumonia, in which foci of suppuration alternate with areas of consolidation chiefly fibrinous in character.

The kidneys show congestion and some evidences of chronic change.

The liver has a slight degree of chronic congestion.

The stomach shows in its lesser curvature 5 cm. from the pylorus a large old ulcer which has perforated but is shut off by adhesions from the general peritoneal cavity. There is chronic gastritis.

The other organs show only slight changes.

The obliteration of the right and left innominate veins obviously necessitated the return of all venous blood which they would naturally convey to the heart, with the possible exception of a small amount carried from the right subclavian vein by the narrow and tortuous remnant of the right innominate, by anastomotic branches connecting the innominate veins with branches of the inferior vena cava. This was effected chiefly by the intercostal branches of the internal mammary veins, which by anastomosis with the superficial epigastric veins established a communication through the saphenous openings with the femoral veins, and thus transmitted the blood from the upper extremities and head through the iliac veins and inferior vena cava to the heart. The presence of a large gastric ulcer which had perforated without giving symptoms sufficiently severe to be remembered by the patient is a feature of interest.

NEW YORK HOSPITAL.

DERMOGRAPHIA AND ANIDROSIS.

BY E. V. MOCK, M.D.,

CAMBRIDGE, ILL.,

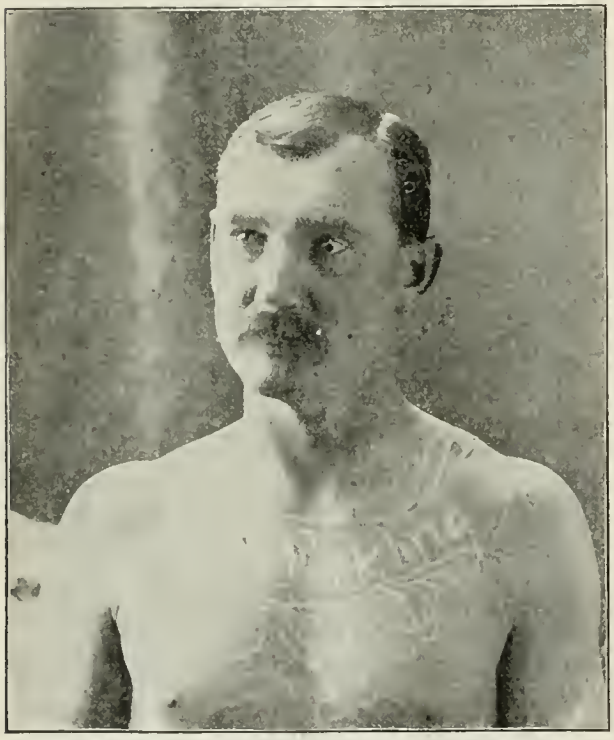
LATE SURGEON TO THE ALMS- AND WORKHOUSE HOSPITALS, BLACKWELL'S ISLAND, NEW YORK.

A CASE of peculiar interest having recently come under my observation, I present a photograph and short history of it.

William F——, thirty-five years old, born in the United States, of Irish parents, married, with healthy children, weighs one hundred and seventy-four pounds. The family history is good, the only disease being a slight eczema on the father's side in the latter years

of his life. The patient has never been ill since childhood, and is a muscular man as shown by the photograph. For a great many years it has been his custom to plunge into a pool of cold spring water in the summer, and this often while he was excessively hot from farm labor. About six years ago he noticed a diminution of perspiration, and in summer suffered unusually from the heat. About three years ago he noticed that a slight contusion of the skin, over the areas where perspiration was diminished, would produce a welt, and that the patches were enlarging; which they did until his entire body was in that condition. Objectively there is no perspiration of the skin of the entire body, but there are no other symptoms, and the patient suffers nothing but from his nonresistance to heat. The welts shown in the photograph are about one-half inch wide and one-fourth inch deep. They were produced by tracing on the skin with the blunt end of a wooden penholder and were photographed about ten minutes later. They remain distinct for about two hours, and at the end of three hours there is no trace of them.

On account of not perspiring and the resultant nonresistance to heat, the patient applied at the Presbyterian Hospital, Chicago, for treatment, and was admitted at the clinics of the Rush Medical College and other places, but no diagnosis was made.



AN ACRANIAL MONSTER.

By ALBERT S. PAYNE, M.D.,
MANISTEE, MICH.

On March 25, 1900, I was called to see Mrs. C——, aged forty years, multipara. She says she was never sick. She is the mother of four living children and has had nine miscarriages and abortions, one at two months, three months, five months, six months; two at seven months; two at eight months, and the one I was called to attend at seven and one-half months. I found an excessive amount of liquor amnii. The head presented, and the woman was delivered in three hours of a monster. The fœtus weighed four and one-half pounds, and was a female with sexual organs well developed. The entire body up to the neck was normal, except the spine. The posterior arches and spines

of the vertebræ were absent down to the sacrum. The defect was covered with a thin membrane for an inch on each side of the spinal cord in place of the skin, and at the edge of this membrane on the skin was a narrow fringe of hair an inch or more long, extending down to the ninth dorsal vertebra. The cord was only rudimentary and ran along under the membrane. The neck was absent, and the cord ran over the anterior part of the foramen magnum, all of the posterior part of the foramen and the occipital bone being absent, as were also the parietal and frontal bones.

The superciliary ridge and all that goes to make up the roof of the orbit were absent, the lesser wing of the sphenoid being the highest bony point. The ethmoid bone ran forward and connected it with the nasal bones. The palatine arch was cleft. No traces of the cerebrum, cerebellum, or medulla existed, although what appeared to be nerves ran across the bone where the foramen magnum should be, and over the bony tissue. The accompanying illustration is from a photograph showing the posterior aspect of the monster.

I could get no history of any previous illness of the mother, and she appeared to be the picture of health. She stated that she always had an excessive amount of fluid while carrying her children. She also stated that she felt life up to the morning when the fœtus was born.

Surgical Suggestions.

Ingrowing Nail.—Pack the side of the nail with cotton soaked in—

℞ Liq. potassæ ..... ℥ i.
Cocaine sol. (4 per cent.) ..... ℥ iij.

Apply plaster strips to draw the soft tissue away from the nail margin. Never cut the side of the nail.—*Medical Times.*

Sprained Ankle.—Apply very hot water followed by a rubber bandage.

Chronic Cervical Metritis.—

℞ Potass. iod.,
Potass. brom. ..... āā gr. xx.
Tr. iodi ..... ℥ ss.
Aquæ ..... ℥ ij.

Inject into the hyperplastic tissue by means of a long syringe.

Pruritus.—Electric souffle: The point of the electrode may be slowly passed over the affected region for twelve to fifteen minutes.—Monell.

Anæsthetic Hæmostatic Solution.—

℞ Gelatin. pur. 2.0
Sodii chloridi 0.7
Acidi carbol. cryst 0 1
Eucain. hydrochlor. B 0.7
Cocain. hydrochlor 0 3
Aquæ destill ..... ad 100.0
M. S. To be used as in the Schleich infiltration anæsthesia.

—Le Grand.

Hypodermic Cure of Hernia.—The fluids are as follows:

℞ Zinc sulphate ..... gr. xx.
Creosote (b. w.) ..... gtt. xv.
Hamamelis ..... ʒ iij.
Glycerin ..... ʒ iij.
Cocaine hydrochlorate (4 per cent. sol.) q.s. ad ʒ i.
M. S. Inject five to twenty minims.

℞ Zinc chloride ..... gr. xx.
Sodium chloride ..... ʒ i.
Cocaine hydrochlorate ..... gr. x.
Glycerin,
Aquæ dest. ..... āā q.s. ad ʒ i.
M. S. Inject four to forty minims.

If the patient is a male, invaginate the scrotum upon the index finger of the right hand, find the external ring; have him draw up his feet until his thighs form a right angle with his body, holding the knees closely together. Pass the finger now into the canal. If the sac has not followed the bowel into the peritoneal cavity, press it upward and outward. Locate the outer margin of the internal ring, and inject six to ten drops at the necessary depth. Apply a truss before the patient rises. Repeat in two days on opposite side of the ring, avoiding the epigastric artery and vein. Three days later repeat half-way down the canal on the side of Poupart's ligament. Further injections may be required.—W. N. Holmes, in *Eclectic Medical Journal.*

Simple Chronic Nasal Catarrh. — Hygiene: Cleanse with alkaline solution, and apply two or three times a week:

℞ Iodi ..... gr v.
Potass. iod ..... gr xv.
Glycerini ..... ʒ i.

Then apply as a protective:

℞ Menthol ..... gr. v.
Camphoræ ..... gr. xx.
Albolene ..... ʒ ij.

—E. B. Gleason.

Toothache.—

℞ Chloroform,
Linim. aconiti,
Tr. capsici ..... āā 30
Ol. caryophylli,
Camphoræ ..... āā 20
M. S. Apply a few drops on a pledget of cotton.

—*Bull. Gén. de Thér.*, June 23d.

Contusions.—

℞ Menthol 3
Collodion 27
M. S. Paint on once or twice a day, but not over joints.

Stings and Bites.—

℞ Ac. salicylic 1
Collod. elastic 10
M S. Apply at once to prevent inflammation.

Boils, Carbuncles, and Felons.—

℞ Ol. oliv. opt ..... ʒ xv.
Plumbi oxidi ..... ʒ iij. + ʒ vi.
Ol. lavandulæ ..... ʒ ij.

This is Hebra's diachylon ointment, which may be applied instead of employing the knife.—Bulkley.

Cholæmic Bleeding.—(1) A solution of gelatin increases the coagulability of healthy and pathological blood. (2) This occurs after local application and subcutaneous administration. (3) It is harmless if antiseptic precautions are carefully carried out. (4) It can be used in all cases of bleeding from the most various causes. (5) Its value as a prophylactic before operation can be established only after further experience. (6) For subcutaneous injection, a one- or two-per-cent. solution is best; for local application, a five- to ten-per-cent. solution at a temperature of 98° to 100 F. (7) It must be sterilized. (8) Heart and kidney disease contraindicate its use.—Kehr.

To Loosen Adhering Dressing pour on peroxide-of-hydrogen solution.

In Inoperable Uterine Cancer.—Make an opening into the rectum for the fetid discharges so that they are under the control of the sphincter ani.—Kuestner.

Styptic for Bleeding Gums.—

℞ Tr. krameriæ ..... ʒ i.
Chloroformi ..... ♏ viij.
Ac. tannic.,
Menthol ..... āā gr. iv.
Aq. destill ..... ʒ ij.

—Viau.

Bone Grafts.—Ricard's plan is preferable to the use of metallic substances. Bone is finally absorbed and replaced by firm fibrous tissue. Bone taken from an animal is better than that from the patient.—Berger.

Abortion, whether threatened, complete, or incomplete, requires artificial dilatation and emptying of the uterus whenever its cavity becomes the source of septic intoxication as indicated by rise in pulse and temperature and foul secretions.—Fothergill.

Gall Stones —Introduction of cannula, probing, withdrawing fluid from the gall bladder, and massage for getting rid of stones are dangerous practices compared with the good accomplished. Surgical operations present the only safe and radical cure.

Infected Wounds are best cleansed with a new hydrogen peroxide (thirty per cent. by weight) equivalent to one hundred per cent. by volume. A one-per-cent. solution may be used for irrigation and application on compresses.—Bruns.

Aneurism.—In nine cases injected with gelatin no patient was cured; only one was considerably improved, but pressure symptoms were generally relieved, and the treatment affords sufficient amelioration to make it deserving of further trial.—Futcher.

Cancer of Uterus.—Curettage. Divide the vagina on all sides an inch below the diseased area. Bring down the uterus and bisect it. Cut the most affected half in two horizontally at the cervical junction. Clamp the uterine artery and remove the quadrants, commencing with the upper, including ovary and tubes. —Kelly.

Anæsthesia.—In all combination of anæsthetics the patient is subjected to the bad effects of all. These admixtures, therefore, possess no advantages, since all the bad effects are exerted upon the heart or kidneys.—R. C. Kemp.

Divided Bowel in the course of operation is closed in the simplest manner by cutting across just beyond the clamp; the bowel being separated for from 2 to 3 cm. from its mesentery. A purse-string suture is inserted through the serous and muscular coats just above the clamp. The clamp being removed, the divided end of the bowel is pushed into the lumen while the circular suture is tightened and knotted.—*Centralbl. für Chirurg.*, May 19, 1900.

Medical Items.

Cheap Dwellings for Workingmen in France.—The *Revue des Revues* for April has a paper on cheap dwellings for workingmen, by M. de Novion. The question of the housing of laborers and cheap means of transit for them is of first importance in England and in France. Industrial building-societies have been formed not only in the suburbs of Paris but at Marseilles, Lyons, Bordeaux, and almost all the large centres of French industry. These societies have built near the towns groups of cottages surrounded by gardens, in which workmen may live cheaply and healthily.

Horse Sickness.—A possible method of prevention of horse sickness, which is endemic in the Orange River colony, Transvaal, Rhodesia, and Bechuanaland, and also occasionally in Cape Colony, is described in the *Cape Times* by Dr. G. C. Purvis. Fortified serum derived from immune horses almost invariably produces fatal hæmoglobinuria when injected into horses suffering from horse sickness. Dr. Purvis finds, however, that if the animal is gradually accustomed to the toxin until it can receive an injection of 100 c.c. or 200 c.c. of serum, virulent blood can be injected without any danger. It appears that fortified serum is a useful agent if used in the proper way, and that it is capable of preventing the onset of horse sickness. Moreover, if in spite of precautions an animal acquires the disease, judicious treatment with the serum will assist in bringing about a cure.

Saloons and Tuberculosis.—Dr. J. Wheatley, medical officer of health, Blackburn, England, in his annual report just issued states that no places, excluding the workrooms of some trades, are more favorable to the spread of tuberculosis than saloon parlors and other frequented rooms of saloons. This is not to be wondered at when one considers the filthy habits as to expectoration too common among those who frequent these places, and the neglect of cleanliness that often obtains with the people in charge of the lower class drinking-places. He urges most scrupulous cleanliness in the management of these places.—*Lancet.*

Ages of Immigrants to this Country of the Leading Nationalities.—It is an interesting fact that nineteen per cent. of the total number of immigrants who came to the United States from the principal countries of Europe during the twenty years closing with June 30, 1898, were under fifteen years of age; that 71.5 per cent were between fifteen and forty years of age, and that 9.5 per cent. were over forty years of age. Considered as to nationalities it appears that Germany has sent the largest percentage of children, as 24.2 per cent. of those who came from that country were under fifteen years of age. Next in proportional order are: Russia and Poland, 23.2 per cent.; Scotland, 21.5 per cent.; England, 21.1 per cent.; Austria, 18.3 per cent.; Norway and Sweden, 16.4 per cent.; Italy, 14.4 per cent.; Hungary, 12.1 per cent.; Ireland, 11.7 per cent. Ireland, Hungary, Norway, and Sweden have supplied during the period mentioned above the largest percentages of immigrants between the ages of fifteen and forty years, being 81.6, 79, and 76.5 per cent. respectively. The next highest proportionately is Italy with 72.1 per cent. Then follow Austria, with 72 per cent.; Russia and Poland, 68.9 per cent.; Scotland, 68.6 per cent.; England, 68.1 per cent.; Germany, 65.3 per cent. In the twenty years Italy has furnished the maximum percentage of the immigrants over forty years of age, or those who have passed the prime of life, this proportion being 13.5 per cent. The lowest proportion was in the immigration from Ireland, it being 6.7 per cent. England's proportion was 10.8 per cent.; Germany's, 10.5 per cent.; Scotland's, 9.9 per cent.; Austria's, 9.7 per cent.; Hungary's, 8.9 per cent; Russia and Poland's, 7.9 per cent.; Norway and Sweden's, 7.1 per cent.—*Bureau of Labor Statistics.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended July 26, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Alaska, Cape Nome	June 20th to July 10th	5*	
District of Columbia, Washington	July 14th to 21st	1	
Indiana, Michigan City	July 14th to 21st	1	
Kansas, Wichita	July 14th to 21st	..	1
Kentucky, Covington	July 9th to 15th	3	
Louisiana, New Orleans	July 14th to 21st	8	2
Massachusetts, Fall River	July 14th to 21st	2	
Lowell	July 14th to 21st	2	
Minnesota, Minneapolis	June 30th to July 14th	23

AMERICAN MEDICINE.[1]

By A. JACOBI, M.D.,
NEW YORK.

IT is the purpose of this address to contribute to your knowledge of transatlantic medicine and medical men. That is why I have to ask the pardon of both my countrymen and all of you, but mainly that of the French gentlemen here assembled, for using (or, perhaps, misusing) a language not my own, but better known to most of you than mine.

The first advisers in cases of sickness, all over New England at least, were the clergymen. Indeed the first news we have of diphtheria in that region came from them. John Rogers and John Fisk are known to have been preachers and doctors. John Foster, of Boston, wrote the first medical treatise published in America in 1677 ("Rule to Guide the Common People of New England How to Treat . . . Smallpocks or Measels"). What might have been expected when real doctors took possession of the field occupied by the clergy did, however, not occur. For a long time the latter remained the staunch friend of the medical practitioner. The Rev. Cotton Mather in 1721 strongly favored the inoculation of smallpox, and defended and protected Dr. Boylston, who was persecuted by the mob of Boston for having a mortality of two per cent. among those inoculated compared with one of fourteen per cent. among those suffering from genuine smallpox. That is different now, when there is no trade or profession more fond of sectarian medicine and medical dilettanteism than the clergy.

The first physicians in the colonies came from abroad. Wooton in 1607, Russell in 1608, appear to have stayed but a short time, for it is reported that when John Smith was wounded he had to go to England to be treated. The name of Lamontagne is mentioned in 1637, John Clark, of Boston, in 1638, Child in 1644. There was but very little opportunity to learn in the seventeenth century. We know of no lectures except those of Dr. Giles Firmin, who lectured in Harvard in 1647 on human osteology. At that time medical practice was learned in apprenticeships; young men would serve and study with a practitioner from three to seven years, the same time that Jacob slaved for Rachel without getting her after all. This system of apprenticeship was continued with more or less modification until recently. Indeed, most medical schools would until lately accept the apprenticeship with a preceptor in lieu of a year's college course. But in those early times those who had the means. and the ambition of learning, went abroad to Leyden, Paris, Padua, or Great Britain.

Our first information in regard to medical lectures refers to those on anatomy. Evidently that subject struck the imagination of chroniclers most forcibly. Dr. Thomas Cadwallader instructed Philadelphia students between 1745 and 1751, so did Dr. John Bard and Peter Middleton in 1750 in New York, Dr. William Hunter in 1752 in Newport, R. I., and Dr. William Shippen in Philadelphia in 1762, until 1765, when the Medical College of Philadelphia was founded. He lectured on anatomy and midwifery, in agreement with the time which did not abhor the incompatibility of anatomy and obstetrics. Historical justice compels me to add right here that it was a professor of anatomy in Harvard University, our famous poet Dr. Oliver Wendell Holmes, who in 1843, long before the unhappy Semmelweis, proclaimed the contagiousness of puerperal fever and the incompatibility of the lying-in room and the dissection table. It was the same Shippen who tried to establish a school of midwifery. There were two medical schools established before the War of Independence, one in Philadelphia in 1765 and one in New York in 1768. The first degree conferred in medicine was that of bachelor of medicine in 1768; the first degrees of doctor in medicine were given in New York to S. Kissam and Robert Tucker in 1770. Before 1776, when the war suspended them, these two institutions conferred fifty-one degrees. The Medical School of Harvard was founded in 1782, Dartmouth, N.H., in 1797, and Lexington, Ky., in 1799. Thus in 1800 there were five medical schools in what then was the United States. In New York the names of the professors were Richard Bailey, John R. B. Rogers, Wright Post, William Hammersley, Samuel L. Mitchell, and David Hosack.[1]

The Medical School of King's College in New York (the name formerly carried by Columbia) was discontinued, but in 1860 the College of Physicians and Surgeons, which was founded in 1807 simultaneously with the School of Medicine of the University of Maryland, took its place as a nominal, a few years ago as an actual, part of Columbia University. Of the 156 medical schools which exist at the present time, 3 date from 1765 to 1800, 12 from 1801–1825, 22 between 1826 and 1850, 33 between 1857 and 1875, and 86 since. How many more have been so good as to disappear from the face of the American earth nobody cares to learn or to know; if we knew, we should shed no tears.

In 1899 there were 156 medical schools in the United States with 24,119 students; the latter have increased one hundred and forty-two per cent. in twenty-one years. Of the 156 schools 21 call themselves homœopathic, with 1,833 students, 7 eclectic with 582, 3 physio-medical with 85 students. I hope nobody will ask me for an explanation of the three last terms, in this year 1900; for I could not give one. Of the 156, 74 are departments of colleges and universities, 82 are separate institutions, and 152 grant degrees. In addition to these 156 there are 10 medical schools for graduates, who come to the larger cities, mostly New York, for the purpose of taking

[1] Abstract of an address delivered before the Thirteenth International Medical Congress, Paris, August 2–9, 1900.

[1] David Hosack graduated in Philadelphia in 1791, and afterward studied abroad. He brought home with him a cabinet of minerals, and a herbarium. He helped in founding the Historical Society of New York in 1804, and maintained the Elgin Botanical Gardens between Forty-seventh and Fifty-first streets, and Fifth and Sixth avenues, which now forms part of the valuable property of Columbia University (Sidney H. Carney, in the *Medical News*, February 17, 1900).

courses mostly in specialties. In 1899 these 10 schools had 1,916 students, of whom 75 were women.

Of the 10 graduate schools, 3 are in Illinois, 1 in Louisiana, 4 in New York, and 2 in Pennsylvania. Less than 2,000 physicians are taught in these institutions annually, most of them in short courses. They employ 300 professors and 3,811 adjuncts and instructors. There can be no doubt as to two effects: first, a good many practitioners of the country have a more or less brief opportunity to improve themselves; secondly, a good many practitioners of the large city bask in the sunshine of the professorial dignity. Sometimes it seems as if plain doctors were scarce at present. But there are some left.

At the time of the War of Independence there were probably 3,500 physicians among the three millions of inhabitants of the colonies. It is estimated that 400 had received medical degrees. In 1798 16 doctors of New York died of what was called the plague; there were 94 in New York in 1800.[1] At present we have probably 120,000 practitioners in the United States.

The ratio of physicians to population is less than 1 to 600 in our country, while in Great Britain it is 1 to 1,100, and in Russia 1 to 8,500. Proportionately we have four times as many physicians as France, five times as many as Germany, six times as many as Italy, and six times as many medical schools as either of these countries. Medical teaching, however, will be better, and more uniform, and more in accordance with the real requirements of the people, when our one hundred and fifty-six schools will have been reduced to twenty-five, and each of them will be connected with a university as its medical department.

The earliest law[2] relating exclusively to physicians was passed by Virginia in 1639, but like the later act of 1736 it was designed mainly to regulate their fees. The act of 1736 made concessions to physicians who held university degrees. In only two of the thirteen colonies were well-considered laws enacted to define the qualifications of physicians. The General Assembly of New York in 1760 decreed that no person should practise as physician or surgeon in the city of New York till examined in medicine and surgery and admitted by one of His Majesty's council, the judges of the supreme court, the king's attorney-general, and the mayor of the city of New York. Such candidates as were approved received certificates conferring the right to practise throughout the whole province. A similar act was passed by the General Assembly of New Jersey in 1772.

In 1840 laws had been enacted by the legislatures of nearly all the States to protect citizens from the imposition of quacks. Between 1840 and 1850, however, most of these laws were either repealed or not enforced, as a result of the cry that restrictions against unlicensed practitioners were designed only to create a monopoly.

The power to confer degrees differs in the various schools of the forty-five States composing the Union. Low standards in many professional schools[3] are due to a failure to subject the degree-conferring power to strict State supervision. In New York and Pennsylvania the laws now prevent an abuse of the power to confer degrees. A similar bill, strongly advocated by educators, was defeated in Illinois through the efforts of politicians and others in favor of low standards. In Ohio and Nebraska the statutes require only the nominal endowment of $5,000 for a degree-conferring institution. In other States and Territories, as a rule, any body of men may form an educational corporation with power to confer degrees, without any guaranty whatever that the privilege will not be abused; from all of which you infer that it is impossible to judge of the Union from a single State.

The power of every medical school to give the license to practise together with its degree of doctor in medicine, led to the furnishing of the country with low-grade practitioners. It is true that mainly in the Eastern States a few colleges gradually improved their methods of teaching and lengthened their curricula, but they were exceptions to the rules. On the other hand, some of the schools in our very New York opposed bitterly every attempt at progress. This progress is due, not to the schools themselves, but to the influence of the medical profession that forced the schools to improve their medical instruction. As early as 1837 in Philadelphia, and 1839 in the Medical Society of the State of New York, it was resolved that teaching and licensing should be separated. This movement resulted in a call for a convention of delegates from all medical schools and societies in the United States. This convention of 1846 led to the formation of the American Medical Association, and was the forerunner of many attempts at giving us better doctors and better schools. The Association of American Medical Colleges that was founded in 1890, the American Institute of Homœopathy of 1844, the National Confederation of Eclectic Medical Colleges of 1871, and the Southern Medical College Association of 1892 deserve credit for earnest efforts in that direction. The greatest difficulty is found, as I have said, in the different standards of the people of our vast territory. Indeed every century and every people has exactly the doctors it deserves, just as it has the rulers it deserves. That is why it is so difficult to arrive at a uniform standard all over the United States, and to arrange a reciprocity between the single States which would allow the doctor of one State to settle in another.

Instruction.—The course of instruction has undergone great changes. A few dozen years ago the so-called seven branches of medicine were taught in didactic lectures, repeated annually, to unprepared young men. There was no laboratory, and but little clinical work. At present the curriculum of all good schools extends over four years, and includes systematic and compulsory work in laboratories, chemical, pathological, histological, and bacteriological, and furnishes better clinical instruction, no longer exclusively to large classes with no means of independent examinations on the part of the student. Moreover, the studies are graded, progressive from year to year, and in many schools the students are examined from year to year

Forty or fifty years ago hardly any systematic clinical instruction was given in the best of our schools. Now, together with obligatory laboratory work, clinical teaching bids fair to assume the leading part in our instruction. But we are far from having European facilities. For what governments do for you, we, who have but very few endowed medical schools, have to rely on the efforts of the profession and the benevolence of those who appreciate the good that is done to mankind by medicine and the medical profession. Until a few years ago all sorts of educational institutions were benefited by philanthropists to the exclusion of medicine. Some change has taken place in that. From 1894 to 1898 the most notable gifts and bequests amounted to $2,631,000 for medical schools and $16,593,701 for hospitals. The new medical school, situated in New York, of Cornell Univer-

[1] Dr. Sidney H. Carney tells us that about that time the gold-headed cane was still pretty universal, but small clothes disappeared rapidly and pantaloons took their place. He also tells us something of their pay. In Bellevue Hospital the attendants on plague cases received 20 shillings daily; at that time the hospital was three miles out of town. A visit among the people cost $1, a visit and dose of medicine $1.25, pills 12 cents; for going a mile out of town $1 extra was charged, to Brooklyn $3, to Staten Island $10. A venesection was paid with $1 to $5.

[2] Henry L. Taylor (under direction of James Russell Parsons), "Professional Education in the United States," p. 362.

[3] "Professional Education," by James Russell Parsons, Jr.

sity, has been presented with $1,500,000 by a single benefactor. In the city of New York alone the names of Vanderbilt, Sloane, Carnegie, Ottendorfer, Woerishoffer, Seth Low, Payne, and Pierrepont Morgan are not the only ones that should be mentioned and never forgotten. This, however, is not all. Only two years ago an unknown benefactor presented Columbia University with a fund wherewith to establish a ward in Roosevelt Hospital for the bedside instruction in the diseases of children, for the medical students.

Benevolence is even more special than this. Mrs. Caroline Brewer Croft left $100,000, which, however, were reduced by the English heirloom tax, to Harvard University on the condition that the income thereof should be spent on researches on the etiology and cure of cancer; the same purpose for which the legislature of the State of New York has, for some years past, spent a large sum annually to be used by Roswell Park of the University of Buffalo. Special hospitals are either endowed or benefited in a similar manner. The cancer hospital of New York was established, or strengthened, by money given by Mrs. Collum and Mrs. Astor many years ago.

Teaching.—Who were the teachers? In by-gone times a few, mostly seven, practitioners would combine to form a school; legislative approval could be had for the asking; they were our "professors." That position gave them prominence in public and increased their private practice; that is why the salaries, if there were any connected with their places, were commensurate with their possibilities to make money outside. Now and then the anatomist got more because his office took more of his time. Thus it happened that medical teaching was considered subordinate to other occupations even in good schools. There are but few men of those times who are remembered because they were teachers; my old friend Alonzo Clark, one of the most learned, intelligent, and eloquent professors the College of Physicians and Surgeons ever had, was almost forgotten before he died, not twenty years ago, and Austin Flint is better remembered by his text-book than by his personal teaching.

The systematic study of pathological anatomy and other so-called exact branches of medicine, histology, bacteriology, etc., is comparatively young. After all they are young all over the world. Fifty-two years ago, when in Germany and wanting to learn something about pathological anatomy, I had to go to Göttingen to listen to Frerichs, the only man who taught it in Germany besides Virchow in Wurzburg, and Rokitansky in Vienna (then belonging to Germany). These studies began in our America at a very opportune time. T. Mitchell Prudden and William H. Welch had each a small pathological laboratory in New York in connection with the medical schools to which they belonged more than twenty years ago, but the systematic study and teaching commenced with the first development of the ideal of a university. This ideal was first realized by the Johns Hopkins University, at Baltimore. From that time on remarkable changes took place in the configuration of most of our medical schools. Pathological anatomy became of fundamental importance; full professorships of that branch were established in most great schools, and, moreover, dozens of laboratories both for teaching and for research. Besides, many of the hospitals were supplied with pathological and clinical laboratories which vie with those of Europe, assistantships and fellowships were increased, and the students were taught to appreciate the new opportunities given and demanded by modern medicine. As far as T. Mitchell Prudden in New York is concerned, the volumes of publications emanating from the beautiful laboratory of the College of Physicians and Surgeons prove his enthusiasm and successes; and never was there a more influential teacher than Welch, who in two brief decades succeeded in disseminating exact research all over the States through his students and followers, who have been called, one by one, to Philadelphia, Chicago, Albany, or Boston. Dozens of them combined lately to celebrate on the 4th of May, 1900, the twenty-fifth anniversary of his graduation as doctor in medicine by a precious volume containing original contributions of the very highest order, an honor to the famous master and an ornament of medical literature. There are in our recent American literature two more such dedicatory volumes of similar import, one containing anatomical papers contributed by his pupils in honor of Professor Wilder, of Cornell University, in 1893, the other mostly clinical, written both by pupils and by American and European colleagues in favor of a New York teacher. In the face of such results, and such enthusiasm, and such love of work, who is there that looks still down on American medicine and American medical men? I am not given to vanity, but proud—that is what I am.

Literature.—According to E. H. Bradford,[1] while the best physicians of the colonies and the young States acquired their knowledge in Great Britain, their books were English. No books grow on the stumps of the forest primeval. When the War of Independence began in 1774, there were 1 book, 3 reprints, and 20 pamphlets by American medical men. To-day there are 7,000 American books and reprints and a countless number of pamphlets; there are annually 300 books and pamphlets and 5,000 journal articles. In one year, 1879–1880, the United States published 10,334, Great Britain 7,476 books and articles. In the catalogue of Harvard University of 1875–76 44 foreign and 13 American medical books were recommended to the students; among the latter there was none on medical chemistry, obstetrics, and surgery; in the catalogue for 1898–99 there are recommended 71 foreign and American books.

The first regular publication of a journal dates from 1790. It carries the following title: *A Journal of the Practice of Medicine and Surgery and Pharmacy in the Military Hospitals of France*, and contains absolutely nothing but translations. For another half-century France was, together with Great Britain, almost the exclusive fountain from which the thirst of American medical men was quenched. The first original journal was *The Medical Repository*, which existed from 1797 to 1824. Not long afterward the first quarterly, then monthly, *American Journal of the Medical Sciences* was founded by Dr. Isaac Hays. These seventy years it has preserved its reputation for its scientific spirit, industry, and conscientiousness. Much that was new, much that is new may be found in its volumes.

Of the large number of quarterlies, or monthlies, I may be permitted to mention the *University Medical Monthly*, of Philadelphia, the *Albany Medical Journal*, of Albany, the *Post-Graduate*, of New York, and the *Therapeutical Gazette*, of Philadelphia, not to speak of special journals, such as the *Annals of Surgery*, the *Archives of Pediatrics*, the *Journal of Obstetrics and the Diseases of Women and Children*, the *Archives of Ophthalmology and Otology*, the *Journal of Cutaneous and Genito-Urinary Diseases*, the *Journal of Nervous and Mental Disease*, and many others, some of which are now and then quoted in Europe, all of which deserve more attention than they have hitherto commanded.

There are, in every nation, some publications which in their individual spheres demonstrate the very best that can be accomplished, and by which the intellect and industry of a people should be measured. Such proofs of the achievements in medicine in America are

[1] Boston Medical and Surgical Journal, June 29, 1899.

contained in the *American Journal of Experimental Medicine*, edited by Welch, and the *American Journal of Physiology*, edited by Bowditch and others. They are the prides of those of us who have lived through the most important period of the development of American medicine, and equal any of the European productions of similar claims. I know they have met with the unstinted praise and applause of European masters.

As an unavoidable contrast to so much excellence, one cannot help noticing the hundreds of medical journals which appear all over the States. Many are printed with honest intentions, others for the purpose of advertising their editors or of puffing proprietary articles. The growing commercialism of the end of the century grasps every opportunity, and medical, like every other, literature is prostituted in the interest of social, professional, or financial egotism. That is why the three hundred medical or alleged medical journals of the United States could well be reduced to fifty. If that were done, both medical knowledge and ethics and the independence of medical journalism would be served to better advantage. Under the present circumstances the medical publications live more on advertisements than on subscribers; and both the publisher and the editor soothe their ethical and scientific conscience, if it ever existed, with the glitter of gold. I have been told, and have read, mainly in the medical magazines both of France and of Germany, that the same occurs in your countries. I speak, however, of what I know, and I am best informed of what is going on in mine.

Among the most important instructors of the medical profession in our country are the great weekly journals which appear mostly in the large cities, New York, Philadelphia, Boston, and Chicago. Most of them have a large number of subscribers and have existed long. The *Boston Medical and Surgical Journal* has reached its one hundred and forty-second, the *New York Medical Journal* its seventy-first, the *Medical News* its seventy-sixth, the MEDICAL RECORD its fifty-seventh volume. The *Journal of the American Medical Association*, which has appeared these eighteen years, takes the same place in relation to the American Medical Association that is occupied by the *British Medical Journal* in relation to the British Medical Association. It was founded to publish the proceedings of the Association, which from 1848 to 1882 had published thirty-three volumes. The *Philadelphia Medical Journal* was founded by a society of medical men desiring to be independent of the medical publishers.

Contributions to the literature of medicine, not of equal rank, are furnished by the large societies, particularly of the States. Many of them publish annual reports. The American Medical Association published thirty-three volumes before its transactions were collected in its journal. The New York Academy of Medicine has furnished nineteen volumes since 1847, which are found in many libraries of Europe; the College of Physicians of Philadelphia twenty-nine since 1787. The very best, certainly among the best, are the productions of fourteen special national associations which were founded at a period in the life of the American Medical Association when its results did not satisfy the expectations of those who had no time to spare for entertainments, excursions, medico-political wrangling, and other pastimes. These men, most of them of a specialistic turn of mind, and bent upon filling their time with work, congregated into special associations whose members were recruited from the vast territory of the United States. The oldest of these seceding associations is the Ophthalmological, which was founded in 1864. The majority have a limited membership. The Association of American Physicians had originally one hundred, now one hundred and twenty-five; the Pediatric Society forty, now sixty members. The object was to select the working members of the profession only. Thus it has happened that their contributions to literature are very valuable indeed.

The Ophthalmological Association has published until the beginning of this year eight volumes since 1864, the Otological six since 1868, the Neurological twenty-two since 1875, the Gynæcological twenty-three since 1879, the Surgical sixteen since 1881, the Climatological fourteen since 1886, the Association of American Physicians thirteen since 1886, the Orthopædic eleven since 1889, the Pediatric ten since 1889, the Anatomical eight since 1888. The Association of Genito-Urinary Surgeons and the Dermatological Association publish their transactions in the *Journal of Cutaneous and Genito-Urinary Diseases*, the Physiological in the *American Journal of Physiology*.

In addition to these there are volumes of unusual excellence containing the proceedings of the "American Congress of Physicians and Surgeons." The history of this Congress is creditable to Mastin, Pepper, Weir Mitchell, and others who founded it. It is as follows: When all of those fourteen special national associations had existed more or less long, and when among the most comprehensive and philosophical minds of the nation the fear of unchecked specialism became more terrifying, it was resolved, among universal applause, that the "*disjecta membra*" should unite once every three years into a congress whose meetings were to be held in Washington, while the selection of the time and place of the two intervening annual meetings of the individual societies was left to their own discretion. In this way the union and unity of medicine were recognized and re-established.

Books are numerous and of about the same nature as in Europe. Text-books for students on all possible subjects, some of them masterpieces, some indifferent, some catechisms which, with their questions and answers, appear to be compounded by idiots for the use of idiots—"que c'est un plaisir de se voir imprimé," says Molière—they all appear to find a market. It is perhaps invidious to select, but I may here say in a general way that some of our text-books in medicine, obstetrics, materia medica, diagnosis, embryology, and many other branches compare favorably with yours. Monographs we have not so many as you; probably for the reason that the number and the variety of our many weekly and monthly journals devour whatever monographic essays have been prepared. Cyclopædias we have like you. It is very fortunate that the publishers, who mostly were the first to give the idea, had no power over their contents. Those edited by Pepper, Keating, Loomis and Thompson, Mann, and Stedman deserve as high praise as those published in Europe. A pleasant feature in medical bookmaking is the occasional participation of the Congress of the United States. Indeed, nearly every State of the Union publishes frequently, at the expense of the people, papers and books of common interest, mostly geological, geographical, and agricultural. Medicine owes to the appropriations of the National Congress, not always given with equal liberality, six volumes of the "Medical and Surgical History of the War," two of "Medical Statistics," seventeen of the "Subject Catalogue" of the surgeon-general's library with its continuations, and the library itself. The "Index Medicus" was not a government publication; at first printed by an ambitious and enthusiastic publisher, it was afterward secured by a small number of subscribers willing to pay a big price. Its final collapse, after twenty years' strenuous labor on the part of Drs. Billings and Fletcher, is not a creditable leaf in the history book of the profession of the United States.

There is, I believe, no country with a greater consumption of journals and books than the United

States. There is probably no village doctor anywhere that has not a library, buys a book or cyclopædia from time to time, and takes one or more journals. What Colonel Stoffel called thirty years ago the instinct of labor in the German government employee, is applicable in some other way to the American medical student and practitioner. They waste no time, are industrious workers and voracious readers.

Medical libraries were founded at an early time. The oldest is that of the Pennsylvania Hospital in Philadelphia; it began in 1762. The library of the New York Hospital was founded in 1776 and transferred to the New York Academy of Medicine two years ago; it then had twenty-three thousand numbers. That of the College of Physicians in Philadelphia, established in 1788, has about fifty-six thousand numbers; that of Boston about thirty thousand. The largest medical library of our, perhaps of any, country is that of Washington, in charge of the surgeon-general of the army; it contains more than one hundred thousand numbers, well selected and in excellent order, accessible to the medical men of the vast country, who I know avail themselves eagerly of the proffered opportunities. It was founded by William A. Hammond during our Civil War, continued and extended by John S. Billings, and is at present in charge of Dr. Huntington. Next in order is that of the New York Academy of Medicine, with about sixty thousand, with duplicates included eighty thousand, volumes. It increases rapidly, partly through purchases out of the income of its library fund of $56,000, partly through donations, and partly through the accumulations of seven hundred medical journals on the shelves of its reading-rooms. Our brethren of the Kings County Medical Society in Brooklyn have just finished a new building in which their rising library has been stored. Smaller medical libraries have been established in at least thirty cities, as far as I know. Large libraries are also in possession of private physicians. A year ago Dr. N. Senn, of Chicago, presented his collection of thirty thousand books to the Rush Medical College. I have knowledge of one library in the possession of a New York physician, of about fifteen thousand volumes.

Ethics.—The ethical conscience of the physicians of the United States is exhibited in a great many ways. It is considered unethical for a doctor to own a drug store or a part of it; ever to take a patent on any invention of his own; ever to recommend over his name a patented instrument, a proprietary food, or medicine, or mineral water. That is illustrated by what happened to the famous Morton after his successful demonstration of the anæsthetic effect of ether in the Massachusetts Hospital. After having extracted a tooth on September 30, 1846, without giving the patient any pain, he applied immediately for patent rights and sold individual office rights. Moreover, he kept his composition, which he called "letheon," a secret. It was then that the profession turned against him and forced him to admit that his "letheon" was sulphuric ether disguised by some aromatic oil. A medical man in America is forbidden ever to advertise his name, or office hours, or his specialty in a newspaper or lay magazine; ever to announce his specialty, if any he have, on his cards. If reports of cases or operations of the same physician appear repeatedly in the public press, it is taken for granted that it has not been without his knowledge, consent, or prompting. All of these things impair a medical man's professional standing; they render him an improper candidate if ever he applies for membership in a medical society, or make him, if he be a member, the subject of discipline.

Many of the rules accepted by American medical men are contained in a book compiled by an Englishman, Percival, in 1807. It was received as the code of ethics of the American Medical Association in 1847, and is still obeyed by those who know the book or who do not know it, or even by those who never knew of its existence. One of the regulations of the code forbids consultations with homœopaths.

It is hardly necessary to say to those of you for whom the practice of medicine is not only diagnosis and autopsy, but the treatment and cure of the patient in whose behalf a consultation is to be held, that when medicinal treatment is in question you cannot agree with a homœopath who is a Hahnemannian; and you do not want to meet a homœopath who, because the name is still fashionable and for a portion of the misinformed public the subject of an almost religious fanaticism, employs that title for meretricious purposes. Still there are cases in which it would be inhuman to refuse a consultation. Not only were such consultations held from olden times, but even in large cities exceptions to the rule have always been frequent, indeed too frequent in my opinion. Moreover, whoever is acquainted with smaller cities and villages, where a homœopath is the only rival or companion of the regular physician, knows that for either it would be suicidal to refuse a consultation. Only lately one of the medical men most widely known for his wisdom, in the American Medical Association and the profession at large, Dr. S. C. Busey, of Washington, proclaimed that the rule forbidding such consultations should be so modified or explained as to permit them in cases of emergency. This is exactly what the Medical Society of the State of New York made its official policy in 1882. We considered it more honest to admit by law what was constantly being done, and to decree precisely that for reasons of humanity and in an urgent case a consultation should not be refused. For this sin we, the body of the Medical Society of New York, were expelled from the American Medical Association.

It would not be proper to dismiss the subject of the position of medical men without referring to them as sanitarians. It is to be taken for granted that all family physicians are sanitarians in the families they have charge of. In their societies public hygiene is frequently the subject of discussion. Practical work in that direction is evidenced by the Sanitary Commission of the Civil War, the effective labors of the New York Academy of Medicine in the reconstruction of the quarantine islands in the harbor of New York, and its defensive work at cholera times; the—it is true, futile—efforts of all the large societies of the country in favor of the re-establishment of the National Board of Health, which perished because a shortsighted Congress refused the required appropriation; and the intelligent activity, under the direction of medical men, of our municipal boards of health. It is true they are hampered by the greed of politicians. Imagine that in New York the president of the board of health must not be a physician! Whether that is more sad or more ludicrous does not matter. The only consolation the citizens of a republic have, when they contemplate such an anachronism, is that they have nobody to blame for it and have nobody to correct it but themselves.

But I do not wish you to believe that we American doctors are altogether angelic. Wings have not grown from our scapulæ yet. We are not such good citizens as you may believe from what I had to praise. Indeed, there is no class of citizens that take less interest in municipal and political, other than sanitary, affairs than doctors. It is true, their vocation takes all their time and is exhausting; but the examples of European parliaments, in which good medical men are representing the people, should not be lost on us. With us, however, most of the medical men in State

legislatures are not the best representatives of the profession from which they claim they came, and whenever there is a medical man in the Congress of the United States, you would not know he was one unless you were told. There is at present a senator of the United States—think of Rome and of Æmilius Paulus and of Cato, think of France and Arago and Nélaton, of Germany and of Virchow—who calls himself a homœopathic physician—no; a homœopathic doctor—and is the staunchest adversary of the medical profession and the solidest champion of the anti-vivisectionists.

Societies.—In democratic communities the free will of the collective individuals takes the place of government dicta. In place of orders coming from above, rules are obeyed that are universally agreed upon by co-operating individuals. That explains the early formation of medical societies in our thinly settled country. Two were formed during Colonial times, viz., the Medical Society of the State of New Jersey in 1766, of Delaware in 1776; in 1876 there was only one State in the whole Union that did not have a State medical society. Affiliated with the State Medical society, and sending delegates to it, there are societies in many of the thirty to sixty or more counties of a State. The State societies hold mostly annual meetings, the county societies monthly or quarterly, according to their membership, isolation, and distances. All of these societies are represented in the American Medical Association, which was formed in 1847, with the exception of the Medical Society of our great State of New York, which has been deprived of its membership since 1882 for a reason to which I have referred.

I should state here that the homœopathic and the eclectic practitioners of the States are legally recognized as separate bodies like ourselves, and are similarly organized. It should also be known that there is a certain relation, legally established, between most of the State medical societies and the legislatures of their States. This legal position is not, however, possessed by the American Medical Association. Yet the voice of that body, powerful through its numbers and the character of its membership, is frequently raised in connection with public questions. So is that of other large societies. The New York Academy of Medicine, for instance, has often been the adviser and co-operator of the official bodies of New York City and State, though originally it was not meant to exercise any such influence. Other societies which in large cities are formed for special scientific purposes have no such influence or activity, and do not claim it.

The number of medical societies in large cities has probably become too large. There are many practitioners who are members in many more than one society. Besides the legalized society of the county—I now speak of New York City—having about fifteen hundred members, there is the "Association of the County," with about eight hundred, and a third one lately formed, viz., the Society of Greater New York. If our brethren would only remember that there is more strength in forceful consolidation than in fanciful expansion or multiplicity! but then it is not always strength and harmony that some men are after, but egotistic self-assertion and envy of the success of others. Besides, we have many societies limited to certain neighborhoods on account of the great distances, and special societies such as the pathological, neurological, ophthalmological, dermatological, obstetrical; also a large and active German Medical Society; and last, but by no means least, the New York Academy of Medicine, which I mentioned before. Let me say a few words about it, for it illustrates some of the differences between America and Europe.

When our New York Academy of Medicine was founded in 1847, it was well understood that it was to differ materially from what is called an Academy of Medicine in Europe. The latter is always a government institution, and in some way or other supported by centralized national means or accumulated funds. Its members comprises the intellectual and sometimes the social heads of the profession only. Young faces are but seldom seen among its fellows. Membership is, as a rule, obtained after a long life of successful scientific pursuits only. Their labors and efforts are not always intended for immediately practical aims or objects, but they become beneficent by the action of that logical force which ordains that there is no scientific result, no truth ever so abstruse, that will not finally terminate in some tangible application. Though all this be true, the limitation and exclusiveness of membership result in a sort of aristocratic estrangement from the masses of the medical profession, and still more from the community at large.

The New York Academy of Medicine has a broader democratic basis. The high and the lowly, the old and comparatively young, the mature and the youthfully ambitious combined for the same purpose. The Academy is not connected with any school or college. It is self-supporting, and carried on in the interest of the whole profession, whether members or not. There are no fees or emoluments of a private or individual nature. It is a democratic community, with equal duties and rights. It is not subsidized by the State or municipal corporation. Its aims are the elevation of the profession to a higher scientific standard for increased public usefulness. Having been a member these forty-three years, I have known it when it was small, and have followed its growth with grateful and hopeful eyes until it was established in its present palace, with its ever-increasing public medical library, second in size and importance in the country; its absence from medico-political fights about the advisability or superfluousness of a written code of ethics; its impartial and non-political interest and co-operation in all public sanitary questions; with its labors in matters of quarantine, cholera, and watershed; with its generosity to members and non-members alike; with its rooms taken up by many large and small special societies so as to form the medical head-centre of the metropolis; and with its ten sections in constant working order. These have given the young and deserving men, during more than a dozen years, the opportunity for legitimate competition, for obtaining a hearing and making their reputations, which are due—next to themselves and their honest work—to the New York Academy of Medicine. Ask me, ladies and gentlemen, for a medical institution, democratic, enlightened, independent, generous, and progressive, the daughter of a country free, independent, progressive, —and I shall give you the name of the New York Academy of Medicine.

Some Facts on Men and Institutions.—During the time of the War of Independence there lived Bard, whose papers on diphtheria are to-day examples of good observation and elegant diction, and Rush, one of the signers of the Declaration of Independence, a fertile writer and famous teacher; a little later Dunglison the lexicographer, Drake, the author of the "Diseases of the Mississippi Valley," and Mitchell; then men like Wormley, whose "Microchemistry of Poisons" appeared in 1867. Contemporaneously there were Bigelow, the inventor of litholapaxy, and Oliver Wendell Holmes, who wrote on the contagiousness of puerperal fever in 1843; then came Harry P. Bowditch, Meigs, Clark, Flint, I. W. Draper, and Beard. Remember, I speak of the dead, of some of the dead only. Of modern times I shall mention no names: but the many studies on malaria, amœbæ, blood, and diagnosis in general, commend themselves to the studious expert.

The literature of these few generations is very fertile; even smaller men did meritorious work. In 1835 it was Fisher, of Boston, who discovered the fontanelle murmur, and in 1832 it was a country doctor in Canandaigua that gave the first plausible explanation of the crepitant râles of incipient pneumonia. What should always be remembered is this, that all the men I mentioned were engaged in the practical work of their profession; and that some of them had enjoyed no other instruction than what the insufficient schools of the country could furnish.

Thus it appears that no faulty system of teaching, no defectiveness of schools, hamper a man whose stimulus is necessity from within, and an ideal. Sometimes this alone is sufficient for unusual results. Think of Marion Sims, and, in spite of his insufficiency as a pathologist, of the impetus his genius gave to gynæcology.

But this is not what is best known in Europe about us. What we are principally credited with is the introduction of anæsthesia into practice.

Dr. Long, of Jefferson, in the State of Georgia, removed a tumor under ether. But it was a dentist, William Jennings Morton, who successfully gave ether to a patient on whom Dr. J. Collins Warren operated for a tumor, in the Massachusetts General Hospital in Boston, on October 16, 1846. Before this assembly of medical men and laymen I confine myself to what Lecky says in his "History of European Morals": "It is probable that the American inventor of the first anæsthetic has done more for the real happiness of mankind than all the philosophers from Socrates to Mills." Nothing remains to be said except that not only was the discovery made in America, but even the name anæsthesia was coined by an American, Oliver Wendell Holmes, great as an anatomist, as a physician, a poet, and a scholar.

Our perfect ambulance system has been largely imitated in Europe; to a small extent also the night medical service for the poor.

Thus, for the humane purpose of medicine you will admit America exhibits a good record. In many other respects it does not excel, but equals Europe. Its hospitals and operating-rooms are like yours; many, I have been told, better than yours. There is no country in which the demands of antisepsis and asepsis are more scrupulously obeyed than ours. The medical attendance on hospitals, however, is capable of improvement. In Europe a distinguished man is known for his lifelong connection with a special hospital. That is less so with us. The ambition to be on a hospital staff, the democratic tendency of the authorities to be fair to the greatest possible number, are the reasons why the hospital staffs are unduly large, and the year is divided up into alternating temporary services, and men are compelled, in order to have hospital services through the whole year, to seek them in different institutions. The improprieties and drawbacks of this arrangement have so long been felt that the establishment of permanent services, mostly of a special nature, has been resorted to in some hospitals. One particular disadvantage of our system of cutting up our hospital services you may have noticed is this, that our hospitals, while being a source of constant improvement to the lucky incumbents of the medical places, have not contributed to medical literature in the shape of special scientific reports, with the exception of the last few years.

The assistantships are in almost every case in the hands of young graduates who obtain their places after competitive examinations. Their terms of service range from one and one-half to two or two and one-half years, in semi-annual advances from grade to grade. This method affords a great many young physicians an opportunity for more or less independent work, guided by their superiors, who make their gratuitous daily visits during their term of service. That is how the people of the United States derive immense benefits from the facilities afforded to a very large number of young graduates before they enter into private practice.

110 West Thirty-Fourth Street.

THE CARE OF PATIENTS DURING SURGICAL OPERATIONS: WITH SOME METHODS OF PREVENTING SHOCK AND INFECTION.[1]

By FENTON B. TURCK, M.D.,

CHICAGO.

Surgery has reached that stage of perfection in aseptic, antiseptic, and operative technique, that it seems there is little room for improvement. Nevertheless, in spite of our most painstaking and apparently perfect precautions, occasionally some disturbing element gains an entrance and death results. In many of the cases terminating fatally, supposedly from infection, the surgeon is perplexed in his search for the true cause or source of the infection. Far too often we hear, "The operation was successful, but the patient died." In these obscure cases, the cause of death is sometimes infection, sometimes shock, and many times the two combined. Shock and infection do sometimes occur in cases in which all the ordinary and usual preventive measures have been taken, the customary precautions being usually found amply sufficient to protect the ordinary case.

I shall lay stress on a few facts which call attention to some of the more insignificant (as they are unusual) but subtle sources of wound infection, and at the same time present some few methods which may tend to diminish the potency of these occasional factors as carriers and sources of infection.

In the preparation for an operation, as, for instance, a laparotomy, all instruments, suture material, sheet and dressings—in fact, inanimate objects—may be rendered completely sterile by means of dry or moist heat. But the animate structures which take part in, or come in contact with, the wound cannot be made absolutely sterile. That the skin of operator or patient is not capable of absolute sterilization without producing death of the tissue cells, has been conclusively demonstrated by many investigators, notably Welch of Johns Hopkins University. Complete annihilation of surface bacteria on the hands of operator and assistants, as well as on the field of operation, is vastly important. In order to attain this perfection in technique, it has become necessary that we have a more thorough knowledge of the bacteria present in or on the normal skin. Much study and investigation have been devoted to this subject by such men as Bizzozero, Bordone-Uffreduzzi, Unna, Maggiora, Mittmann, Fürbringer, Preindlsberger, Robb and Ghriskey, and Welch.

The skin, owing to its location, is constantly coming in contact with some form of contamination from external objects. Many species of bacteria find on its surface a place for development and reproduction. Mittmann mentions seventy-eight different species, of which fifty-six were cocci. Preindlsberger describes thirty-two species, of which twenty-eight were cocci. Maggiora isolated twenty-nine micro-organisms, of which twenty-two were bacteria, three budding fungi, and four moulds. Bizzozero isolated and described the so-called bacillus epidermidis which he obtained from the skin between the toes. Along this line, the following experiments were carried out by the author:

[1] Paper presented to the Thirteenth International Medical Congress, Paris, August 2–9, 1900.

Towels used with the laparotomy sheet were taken after the operation was completed, and small pieces removed. The small portion of towel was dropped into bouillon, and the bacteria were allowed to grow. Three such tubes were made from different cases.

The skin was examined in six cases, as follows: After the usual preparation of the site of operation, the skin was roughly scraped until a mass of epithelial cells was freed. These separated epithelial cells were inoculated in bouillon and in gelatin, sterile cultures. During the course of the operation, small pieces of skin were cut out of the wound margin. These pieces were dropped into bouillon tubes and the bacteria allowed to grow. The growths in all these tubes were practically identical, being composed of a short bacillus, the staphylococcus pyogenes, and other cocci. Cultures of these bacteria were inoculated into animals not in shock and found to be non-pathogenic; while in animals in which shock was artificially produced by exposure and manipulation of the viscera, they were found to be pathogenic. Details of these experiments will be found later on in this article.

The exposed surface is not usually the seat of abundant growth of bacteria, but indentations and folds especially predispose to their rapid growth, as in the axilla, groin, umbilicus, between fingers and toes, and under the nails—this latter location teaches a lesson as to the need of surgical cleanliness.

Welch, in 1891, was the first to call attention to one bacterial species, named by him staphylococcus epidermidis albus, which he regarded as the inhabitant of the normal skin, owing to the regularity with which it was found in cultures from the skin. It is practically similar to the staphylococcus pyocyaneus albus. It liquefies gelatin, slowly coagulates milk, and is feebly pyogenic. It is found along hair shafts in the follicle, in which situation it is able to withstand the ordinary process of disinfection, and remain in place unchanged, in cases in which cultures from surface skin will give a negative result.

Robb and Ghriskey[1] examined stitches in thirty laparotomies and fifteen perineorrhaphies. In thirty-three of these cases pure cultures of staphylococcus epidermidis albus were obtained, and in other cases were found staphylococcus pyogenes aureus, staphylococcus flavus, and streptococcus pyogenes; and in conclusion he says: "We have no sure and absolute method of rendering the field of operation entirely free from organisms, owing to the impracticability of destroying the superficial layers of skin. The staphylococcus epidermidis albus is found in the skin with such regularity that the latter situation may, for all practical purposes, be regarded as its natural habitat, and our methods are not successful in reaching those bacteria in the depth of the structure." It is usually innocuous and is often found in wounds in which healing by first intention has been perfect. But Welch looks upon it as the cause in cases in which slight elevation of temperature and moderate suppuration have been present; and as the most common cause of stitch abscess. Robb and Ghriskey claim that the number of bacteria is increased by use of the drainage tube or other foreign body, too tight ligatures or sutures, and by the presence of any necrotic tissue. They also call attention to the fact that germs are more prone to multiply if catgut is used than if other suture material is employed.

Among the other important bacteria found in or on the skin might be mentioned other white and yellow cocci, and, unless careful study is made of the growth, some of the white cocci may be mistaken for the staphylococcus pyogenes aureus (this later being found rarely anywhere but on the hands of surgeons, surgeons' assistants, and masseurs). Also bacillus pyocyaneus and bacillus coli communis are found rarely in the skin.

The skin of the hand of the surgeon may be protected during the course of an ordinary operation by gloves made of thin rubber. These are capable of absolute sterilization, are water-proof and germ-proof. But the skin of the patient at and surrounding the site of the wound still contains germs deeply situated. An attempt should be made to prevent infection from this portion of skin coming in contact with the wound or from any article or substance which in turn might come in contact with the wound, as effectually as infection from the skin of the operator's hands is now prevented. The usual laparotomy sheets and towels, while far superior to having the skin uncovered, are capable when wet of transmitting infection from the surrounding skin area to the wound margin, or even to the peritoneum or peritoneal cavity; from them infection may be transmitted to the sponge, instruments, or hand which may be placed in contact with them at such times. Again, in cases of resection of bowel, or when pus is evacuated, the ordinary laparotomy sheet is little or no protection to the surrounding skin. The infectious matter is absorbed by the cloth, and it remains in contact with the skin and perhaps the edges of the wound for a greater or less length of time, thus rendering the entire and perfect removal of infectious germs almost an impossibility, and those remaining act in the future as a source of infection. During the course of the operation, these laparotomy sheets become wet with warm water, which soon becomes cold, and the body heat is lowered considerably by evaporation, thus greatly increasing the danger of shock, and, in turn, of infection.

To obviate the above objections to the usual methods of procedure, and also to reduce to some slight extent the danger of shock and infection, it is recommended, after the usual steps in cleansing the field of operation are taken, to place over it a sheet of thin rubber which extends around and fits closely to the body, being held in place by straps and buckles.[1] This is made in different sizes, each with an opening which may be placed directly over the site of incision, or it can be left to be opened by the surgeon as an artificial skin. It fits closely and does not interfere with the field of operation. The usual linen laparotomy sheet may be used in addition over this, if the operator so desires. This rubber protective has the following advantages: (1) It diminishes the danger of infection from the skin; (2) it prevents contamination of the skin; (3) it reduces the tendency to shock by protecting the exposed area of the body and thus preventing the loss of heat by evaporation.

The precautionary measure taken by some surgeons of securing the peritoneum to the skin by means of a few stitches, which leave the intervening edges exposed, does not afford complete protection to the wound margin. If this central opening in the rubber sheet is cut in flaps, these can be folded over the wound margin and into the peritoneal cavity, and held in place by means of a self-retaining retractor. In this way less time is consumed, while the skin and wound margins, as well as the peritoneum, are excluded from the field of operation.

Having isolated the skin and wound margins, it is necessary to consider further protection to the abdominal cavity and the wound edges from possible contamination arising from the opening of a viscus or false cavity. In order to make clear the method for preventing this infection, the operation of gastro-enterostomy may be regarded as the most typical for illustration.

A square sheet of rubber dam is made with two

[1] Bulletin of the Johns Hopkins Hospital, April, 1892.

[1] "Improved Methods during Surg. Operations," Journal of the American Medical Association.

small openings which are reinforced by a rubber band forming a collar, these openings being from three to six inches distant from each other. This protector is laid over the abdominal wound, and that portion of the stomach to be incised is drawn through one of the openings and a loop of intestine for anastomosis through the other. This portion of viscera thus excluded from the abdominal cavity, and the constriction band around each, retard any undue escape of contents, and at the same time keep the contaminating material on the outside where it can be easily removed from the rubber cloth by flushing or other means, and at no time can it come in contact with the peritoneal cavity or other viscera. At the completion of the operation, this shield is readily removed by dividing it with scissors, thus freeing the anastomosis, which is carefully dropped back into the abdominal cavity and the latter closed as the operator prefers.

The steps in an end-to-end anastomosis would be about the same as those above mentioned. For cholecystotomy or a similar operation, a protective with but one opening would be necessary. In an emergency, or when a special protective shield cannot be had, one might be improvised for the occasion from rubber dam, puncturing small round holes where desired. But in this case the constriction at the rings or openings would not be so diffused nor so uniform as in the one specially made. It is obvious that by the use of this shield the following advantages are gained:

(1) Absolute exclusion of the abdominal cavity from the danger of infection (*a*) by escape of visceral contents; (*b*) through outside influences.

(2) Prevention of excessive escape of visceral contents.

(3) Partial if not perfect control of hemorrhage, by the pressure exerted by the rubber band or collar.

(4) Reduction of the liability to trauma of the viscera by handling: (*a*) Being covered with rubber, they are less liable to injury. (*b*) The "collar" holds them simply in position and there is no need of tugging and pulling.

(5) Minimizing of the tendency to shock: (*a*) By being covered, the viscera escape the evil effects of handling. (*b*) Non-exposure of the viscera prevents evaporation, and in consequence there is no desiccation or loss of heat.

In abdominal operations, even when we have used every precaution against infection, there is still another important factor, namely, shock. The use of the word shock may appear unscientific, inasmuch as it represents such a diversity of etiological factors and pathological conditions, with a most complex symptomatology. What is sometimes considered to be shock following an operation may be a form of infection obscured by the symptoms of shock. According to Küster,[1] vaginal methods are less dangerous than abdominal, but though the chief danger of the latter is attributed to shock, as a matter of fact infection of the peritoneum, even when there are no clinical or post-mortem signs of peritonitis, is very often the real cause of death. Autopsies of fatal cases ought to include bacteriological examination of the secretions of the cavity.

It is well recognized clinically that susceptibility to infection is acquired through the shock following serious operations. The experiments on animals by Canalis and Morpurgo,[2] also by Tizzoni and Cattani, establish the above clinical observations, and in even mild forms of shock the subject is more susceptible to the infection that occurs during ordinary abdominal operations. Natural immunity to infection seems lessened or suspended, according to the degree of shock.

[1] British Gynæcological Journal, 1899–1900.

[2] Fortschritte der Medicin, 1890, Nos. 18 and 19.

Aside from the questions of virulence, the point of inoculation, and the dose of infection, we are confronted with the problem of susceptibility or non-susceptibility of the case undergoing operation. Pasteur immersed a hen in cold water, causing her to lose resistence to anthrax. Pertuschy kept a frog at a temperature of 25° and 35° C., causing it to become susceptible to anthrax infection, which resulted in death. In my previous experiments upon dogs in the study of surgical shock,[1] I observed that when shock was artificially produced, the animal was subject to infection following the symptoms of shock. Animals in which surgical shock was reduced, as by the use of heat applied within the abdominal cavity, and also within the stomach, such as the hot-water bag,[2] rarely died from infection. These observations led to a most interesting series of experiments to determine how far high temperatures applied to the abdominal cavity, and also within the stomach, would stimulate the vessels and tissue cells and prevent the growth of pathogenic micro-organisms introduced into the abdominal cavity. Cobbet and Melsome found a comparative local immunity to streptococcus erysipelatis produced by the presence of hyperæmic exudate in a rabbit's ear, from previous inflammatory attacks. Metchnikoff and Issaeff[3] found that by first injecting sterile bouillon into the peritoneal cavity of guinea-pigs, no infection would take place when cholera vibrios or pneumococci were inoculated the following day; but when no such stimulation of the peritoneum had taken place, the animals died from the infection. Walther and Ravighi, cited by Löwy and Richter,[4] rendered the animal hyperthermic and lessened susceptibility to infection. This was also done by Filehne.[5] Walther found that artificial heat applied to the surface prevented infection; Ravighi, that artificial warming prolonged the life of rabbits infected with bacilli of rabbit septicæmia and anthrax bacilli. Löwy and Richter came to similar conclusions by producing hyperthermia by cerebral puncture. The following experiments made by the author seem to indicate that the application of heat by the methods soon to be described not only prevented shock and reduced shock when present in the animals experimented upon, but markedly increased the immunity to infection, while animals in shock, not so stimulated by the action of heat applied to the abdominal cavity or within the stomach, showed increased susceptibility to infection.

In cœliotomies, especially operations on the upper abdominal area, in liver, stomach, and intestinal surgery, this factor of shock followed by infection is one of the most important sources of danger to the life of the patient. In the above-described methods, I have called attention to the manner of preventing injuries in handling the viscera and methods for preventing desiccation of exposed viscera and loss of heat. The application of heat to the viscera is for the purpose of stimulation, and it is usual to apply hot sponges for this purpose. The heat in the wet sponges is soon dissipated, and instead of supplying heat the sponge abstracts it from the viscera and surrounding tissues. The sponges cannot be changed frequently enough to keep up the temperature. To avoid this, I have placed within a gauze pad a small, thin, rubber hot-water bag. These are made in different shapes and sizes for various uses.[6] In some cases the

[1] Journal of the American Medical Association, June, 1897, p. 1160.

[6] Journal of the American Medical Association, June 9, 1900.

gauze is not needed for absorptive purposes, but simply for holding back the viscera. The hot-water bag alone may then be inserted into the abdominal cavity in the shape of a ring, to act as a coffer-dam for the operative field. The rubber bags may be rendered absolutely sterile, and then be partially filled with sterile water and heated in a receptacle or bath to the desired temperature. The degree of temperature which I found most useful is about 48° C.

The value of heat obtained by the introduction of hot water into the abdominal cavity is well known; also that it is necessary to maintain heat. There are many objections to the placing of water directly within the abdominal cavity. The danger of spreading infection is especially important, and it has been claimed that some of the evil results following this method have been due to "flooding" the endothelial layers of the peritoneum; and it is impossible to maintain the heat for any considerable length of time, as it is so quickly absorbed that it no longer acts as a stimulant to the end nerves. With the hot-water rubber pads or bags, we possess all the advantages in preventing shock by heat stimulation, with none of the above-mentioned disadvantages.

There must be a distinction made in the measures resorted to in the prevention of shock when it is imminent, and those when profound shock is present. Of all measures for preventing shock, the application of heat is one of our most valuable agents. In previous contributions on this subject,[1] I have shown that splanchnic congestion in shock is most readily reduced by the application of heat to the splanchnic area.

The advantages of hot-water pads are: (1) The continuous application of heat at the required temperature. (2) They are soft and yielding like a water-bed. (3) They can be changed at will and can be removed through a small opening. (4) At the end of an operation, before the abdominal cavity is closed, a hot-water rubber pad is placed under the line of closure and covered with a small gauze pad to catch any blood or discharge. This bulges the walls upward sufficiently for the more accurate closing of the abdominal wound. In removal, the pad is partially pulled through the small opening at the end of the wound, the water enters the extracted portion, and the bag is easily withdrawn, far more easily than gauze can be dragged out.

Experiments.—Experiment I. Dogs Nos. 1 and 2, brothers; black mongrels nine months old; weight respectively 8 and 9 kgm. The animals were prepared with the usual aseptic precautions.

Dog No. 1: The abdomen was opened and exposed to a draught of air at a temperature of 15° C., for one hour. The viscera were drawn out and subjected to the insult of manipulation, care being taken not to produce any visible trauma. Profound shock resulted, shown by the pallor, slow pulse, coldness of the skin, low temperature, the respiratory and vascular failure, There was marked visceral disturbance. One loop of pure culture of virulent staphylococci pyogenes aureus was inoculated along the upper viscera by stroke culture and along the stomach and upper intestines. Another loop was applied similarly over the lower intestinal walls. A mixture of one loop and sterilized water was sprinkled over the viscera. The abdomen was closed in the usual way. The animal still remained in profound shock. On being placed in a warm room, reaction took place.

Result: General peritonitis and death on the fourth day. Post-mortem showed multiple abscesses, and bacteriological examination showed staphylococci pyogenes aureus.

Dog No. 2: The abdomen was opened and exposed to a draught of air, and the viscera were handled as in the case of the first dog. Small rubber hot-water bags containing 100 c.c. of water were sterilized and placed in the upper and lower portions of the abdominal cavity. The temperature of water in the bags was 50° C. Instead of the bluish congestion of the veins observed in the first animal, they retained more the purple shade, and the viscera assumed the bright crimson shade of simple hyperæmia. Although the viscera were exposed freely to the air, there was no marked embarrassment of the heart and circulation, or of respiration. The body temperature at the end of the experiment (one hour and fifteen minutes) had reached 40° C., rectal temperature. The bags were removed from the abdominal cavity, and a loop of pure virulent culture of a staphyloccus pyogenes aureus was inoculated into the upper portion of the abdominal cavity and a small loop into the lower portion of the abdominal cavity. A loop of virulent culture in 10 c.c. water was sprinkled in the abdominal cavity. The abdomen was closed, no shock being evident.

Result: There was no peritonitis; no infection. The stitches were removed on the tenth day. In three weeks the abdomen was again opened and a gastro-enterostomy performed. A few adhesions were found at the site of the old operation, but no evidences of infection. Bacteriological examination was negative.

Experiment II. Scotch terrier mixture; weight 6 kgm. The abdomen was opened, and the viscera were exposed to a draught of air for one hour and ten minutes. The viscera were handled under aseptic precautions. Evidences of shock were present. I introduced hot-water bags into the abdominal cavity and observed an increase in the action of the heart and circulation within five minutes. The bluish condition of the tongue improved, and a change was noticeable in the mouth. Respiration was still markedly shallow. A hot-water bag containing water at 50° C. was then placed in the stomach. This hot-water bag was attached to a double recurrent tube, and water was allowed to play through it continuously at a temperature of 55° C. As the bag was introduced into the stomach and hot water was forced into the bag, it stimulated the circulation at once, and more chloroform was demanded to increase anæsthesia. When all of the symptoms of shock were reduced, virulent staphylococci were introduced into the upper and lower portions of the abdominal cavity; 10 c.c. of four days' growth in bouillon was also introduced into the abdominal cavity. The abdomen was closed. No evidences of shock were present. Soon after coming out from the anæsthetic, the animal was able to run about without any evident distress.

Result: No infection occurred, and no increase in temperature, and at the end of one month a second operation was performed on the same animal, and the bacteriological examination was negative.

Experiment III. Yellow mongrel, weighing 10 kgm. The abdomen was eviscerated under aseptic precautions, with an exposure of one and one-half hours. The animal showed shallow respirations, pallor, slow heart beat, low temperature, cold surface. All the evidences of shock were present. Pure cultures of streptococci pyogenes were introduced into the abdominal cavity over the walls as well as over the visceral layers. The abdomen was closed. The animal remained in profound shock for several hours. Upon being placed in a warm room, a gradual reaction took place.

Result: Marked septicæmia followed, with diffuse peritonitis; the animal died on the fifth day. Post-mortem showed streptococci in the abdomen and also in the heart.

[1] Journal of the American Medical Association, June 11, 1896; *ibid.*, June 19, 1897. Also Proceedings of the Am. Gastro-Ent. Association, 1900, "Splanchnic Circulation in Relation to the Stomach and Intestines."

Experiment IV. Black-and-white dog, weighing 11 kgm. The viscera were exposed and roughly handled. Hot-water bags were placed within the abdominal cavity in the upper and lower portions of the abdomen—three or four small bags at one time. These were changed at intervals of about ten minutes, or as soon as the temperature of the water fell below 50° C. The temperature of the animal rose to 40° C.; respirations were deep, and the circulation showed peripheral injection of the arterioles, and hyperæmia of all the abdominal viscera as the result of the heat stimulation. Virulent cultures of streptococci were introduced into the upper and lower portions of the abdomen; also a bouillon culture was distributed throughout the abdomen. The abdomen was then closed under aseptic precautions and sealed. There was no shock evident, and the following day the animal ate meat, and seemed to be well. The animal lived for one year after that, with no evidence of infection.

Experiment V. Rabbit weighing 1,500 gm. The viscera were exposed to a cold draught of air for one hour. I then introduced staphylococci pyogenes and sealed the abdomen.

Result: Diffuse peritonitis with localized abscesses.

Experiment VI. Rabbit weighing 2,000 gm. The abdomen was opened and the viscera were exposed; hot-water bags were placed in the abdominal cavity for one hour; temperature of water in bags 50° C. Hyperæmia of the viscera with well-established peripheral circulation took place. Staphylococci were introduced into the abdominal cavity.

Result: The animal recovered without infection.

Experiment VII. White-and-gray rabbit, weight 1,800 gm. The viscera were exposed. Hot-water bags were introduced into the abdominal cavity for one hour; temperature of the water in bags 50° C. Inoculation was with streptococci pyogenes.

Result: General diffuse peritonitis; septicæmia; death. Bacteriological examination revealed streptococci.

Experiment VIII. Black-and-white rabbit, weight 2,400 gm. The viscera were exposed for one hour. A hot-water bag was placed in the abdominal cavity during this time and changed as the temperature of the water in the bags decreased. Streptococci were placed in the upper and lower portions of the abdominal cavity. The abdomen was then closed.

Result: No infection; no peritonitis. Post-mortem was made one month after and no evidences of the inoculations were present.

Experiment IX. Brown-and-white guinea-pig weighing 500 gm. The abdomen was opened, shock produced, and inoculation made with staphylococci.

Result: Death.

Experiment X. Red-and-white guinea-pig. The viscera were exposed, and small hot-water bags were introduced into the abdominal cavity. Exposure was made for three-quarters of an hour. Inoculation was made with staphylococci. No shock was present.

Result: The animal died next day.

Experiment XI. White-and-black guinea-pig. Shock was produced and the animal inoculated with staphylococci.

Result: Death.

Experiment XII. Guinea-pig, weight 750 gm. Death occurred after shock, after infection with streptococci.

Experiment XIII. Guinea-pig. Exposure of viscera was done and a hot-water bag introduced into the cavity. The animal was inoculated with streptococci.

Result: The animal died same night.

Experiment XIV. Guinea-pig. The viscera were exposed and hot-water bags were introduced for one hour. It was inoculated with staphylococci in the abdominal cavity.

Result: No infection. Post-mortem in one week revealed no foci. Bacteriological examination was negative.

Experiment XV. Guinea-pig. The abdomen was opened; also the stomach exposed, and the intestines were drawn out. Desiccation was allowed, and a hot-water bag was introduced; the temperature of the animal rose two degrees.

Result: No shock; no infection.

Experiment XVI. Guinea-pig. The viscera were exposed and a hot-water bag was kept constantly in the stomach. I introduced mixed culture of staphylococci and streptococci.

Result: No shock and no infection.

Experiment XVII. Small yellow guinea-pig, weighing 500 gm. I opened the abdomen and applied heat; heat also was applied to the stomach internally. A mixed culture of staphylococci and streptococci was introduced.

Result: The animal died same evening.

Experiment XVIII. Guinea-pig weighing 600 gm. The viscera were exposed and a hot-water bag was placed in the abdominal cavity and in the stomach; this was continued for forty-five minutes. A mixed culture of streptococci and staphylococci was introduced.

Result: No shock and no infection. Examination at end of two weeks bacteriologically was negative.

Experiment XIX. Under aseptic conditions, the abdomen of a dog was opened and the viscera were exposed for one hour. Staphylococcus albus cultures taken from the skin of patients who had been aseptically prepared for operation were introduced into the upper and lower portions of the abdomen.

Result: The animal died the third day, evidently from shock and infection. Examination showed small foci of growths, which proved to be staphylococci albus, similar to those introduced.

Experiment XX. Scotch terrier, mixed. The abdomen was exposed for an hour, and hot-water bags were introduced into the stomach and abdominal cavity. Staphylococci albus taken from cultures from skin of patients before operation were used, after aseptic preparation.

Result: No shock and no infection.

Same animal one month later: The abdomen was opened and shock produced, followed by attempts at resuscitation with hot-water bags.

Result: The animal died next day from shock and infection.

Experiment XXI. Large black mongrel. Hemorrhage of 600 c.c. was induced. Cannulæ were placed in the femoral artery and jugular vein to measure blood pressure. The venous pressure was not sufficient to raise mercury. There was the characteristic pressure of shock induced by exposure of viscera. The blood pressure fell to 57 mm. A hot-water bag was introduced into the stomach, the water at 55 C. At the end of three minutes the blood pressure was raised to 75° C.; at the end of five minutes it reached 100° C., and at the end of ten minutes had reached 130° C. with an accelerated respiration. The hot-water bag was withdrawn, and the animal was allowed to go under shock again. Observed at the end of half an hour, the pressure had fallen to 80 mm., but upon introduction of the hot-water bag it rose to 140 mm. The bag was again withdrawn for a short time, when the pressure fell to 75 mm. The animal was then infused intravenously with saline solution, 400 c.c. The abdominal cavity was then infected with staphylococci.

Result: The animal died next morning in shock.

Experiment XXII. Mongrel dog fairly well nourished. Gastro-enterostomy was performed. The viscera were exposed and the skin and edges of the

wound covered in with rubber dam. A rubber bag containing water at 48° C. was introduced into the abdominal cavity, this acting as hot pad or sponge to prevent shock. The exposed viscera being protected with rubber dam, small openings were cut in the rubber, and the viscera to be operated upon were drawn through these openings. At the same time, constrictions were made with rubber around that portion of the stomach which was operated upon. The corresponding portion of the jejunum was covered in the same way, it being drawn through a similar aperture in a portion of the rubber dam. The edges of the dam covered entirely the abdominal opening. These excluded air from the abdominal cavity and prevented any injury to the exposed viscera. The operation lasted two hours, the time being purposely prolonged. The jejunum was joined to the stomach by double suture. The rubber dam was found wholly to protect the viscera from contamination from the stomach contents or the contents of the bowel, and at the same time to prevent loss of heat and desiccation of the viscera, thus preventing shock. The rubber dam also prevented leakage from the stomach and intestines, and hemorrhage was averted. After suturing the viscera, the rubber dam was slit and removed. A hot-water bag was then placed underneath the abdominal wall. This, pressing upward against the abdominal wall, held it in place for suture, and at the same time lessened the danger of the viscera coming in contact with the needle. As soon as the suture joined nearly to the upper angle of the wound, a portion of the bag was drawn out through this small opening and the fluid in the bag forced into the extruded portion. The bag was then easily withdrawn. The abdominal cavity was then closed.

Result: The animal showed no symptoms of shock or infection. It was fed meat the following day, and the stomach showed remarkable digestive activity.

Experiment XXIII. Scotch terrier. The abdomen was opened and the viscera were exposed, and hot-water bags were placed in the abdominal cavity. The temperature of the bags was 55° and 58° C. Exposure lasted one hour and twenty minutes. The animal was inoculated with virulent cultures of staphylococcus pyogenes albus. The high temperature produced definite stimulation. After closure of the abdomen and sealing of the wound, the animal escaped and ran four blocks before capture. The exertion caused the animal to vomit bile, and show signs of exhaustion.

Result: The dog died at the end of twenty-four hours. The post-mortem revealed a marked hyperæmia of the stomach and intestines, exudate extending over the upper and lower portions of the abdomen, and mucus at different points. Upon the intestines were found what appeared to be blebs following burns. Cultures were made from the exudates, from the duodenum, and from the small intestines.

Experiment XXIV. Mongrel weighing 7½ kgm. The viscera were exposed and hemorrhage of 400 c.c. was induced. Profound shock followed. An injection of 500 c.c. of saline solution was made subcutaneously, and the animal was sewed up, after inoculation with colon bacilli.

Result: The animal recovered from shock, but died in one week. Colon bacilli were found in the spleen. There was general peritonitis. Death was the result of infection following shock.

Experiment XXV. Dog weighing 8 kgm. The viscera were exposed and a hemorrhage of 400 c.c. was induced. The hot-water bags were placed in the abdominal cavity and stomach, and the animal was infused intravenously with hot saline solution. It was then inoculated with fresh cultures of colon bacilli above and below, and the wound sutured.

Result: No evidences of shock and no infection.

One month later the same animal was subjected to gastro-enterostomy. Bacteriological examination at this time was negative. The animal recovered.

Experiment XXVI. Large setter. I exposed the abdomen and performed gastro-enterostomy. The animal was then inoculated with cultures of staphylococci albus made from the skin of patients after preparation for operation.

Result: Shock from which the animal did not recover; it died on the sixth day of general peritonitis. Staphylococci albus were found which liquefied gelatin in culture.

Experiment XXVII. Large black mongrel. I exposed the viscera and removed one and one-half feet of intestine, following this with anastomosis. Operation was prolonged one and one-half hours, with frequent manipulation of viscera and exposure. Shock was produced. Staphylococci albus obtained from skin of patients before surgical operation were introduced.

Result: The animal died on the fourth day.

Experiment XXVIII. Dog weighing 6 kgm. Evisceration was done.

Result: The animal lived three hours. It had not been inoculated.

Experiment XXIX. Dog. It was placed on a hot-water bed, and the abdomen opened and exposed to a draught of air. The viscera were exposed to the air for forty-five minutes. Tortuous veins stood out in dark relief upon a livid background. There was a marked fall in temperature, and reflexes were absent. The anæsthesia was withdrawn, as none was required. The breathing was shallow, pulse rapid and weak, and tongue pale. The abdomen was closed at the end of one hour and fifteen minutes. The operation was carried out under aseptic precautions.

Result: The animal died in three days.

Experiment XXX. Dog. It was placed upon hot-water bag, and the viscera were exposed to the air until profound shock was produced. Notwithstanding the heat from the hot-water bag, which was 120° C., there was marked visceral congestion with anæmia of the surface, shallow breathing, and loss of reflexes, even after withdrawal of the anæsthetic. The animal was in evident collapse. A hot-water bag was placed in the stomach, at a temperature of 53° C. The water was forced into the bag by a double tube so that the temperature did not vary, and its application was followed by stimulation of the respiratory centre, heart, and circulation. Hot-water bags were also placed in the abdominal cavity. The viscera regained color and lost appearance of venous congestion. The heart became more rapid, the surface warm, and shock was reduced. At the end of an hour and forty-five minutes the viscera were returned and the abdomen was closed.

Result: The animal completely recovered.

Experiment XXXI. Black dog, weighing 13 kgm. The field of operation was prepared aseptically, as in all the other experiments. The viscera were manipulated with rubber gloves. Shock was produced with evidences of collapse; 400 c.c. of physiological saline solution was injected intravenously. The abdominal cavity was inoculated with bacilli taken from the skin of patient over the field of operation after its having been prepared for operation.

Result: The animal died on the fifth day of peritonitis. Bacteriological examination showed a mixed infection.

Experiment XXXII. Dog weighing 14½ kgm. The viscera were exposed. It was inoculated with staphylococci taken from the skin of a patient over the field of operation. The animal was infused subcutaneously with salt solution.

Result: The animal died on the fourth day. Bacteriological examination showed staphylococcus.

Experiment XXXIII. Dog weighing 12 kgm. It was infused subcutaneously with salt solution and inoculated with staphylococcus pyogenes aureus.

Result: The animal died in two days of peritonitis. No cultures were made.

Experiment XXXIV. Dog weighing 13 kgm. The viscera were exposed and shock was induced. It was infused subcutaneously with saline solution, after a hemorrhage of 400 c.c. had been induced.

Result: The animal died on the second day.

Experiment XXXV. Black-and-white guinea-pig. The viscera were exposed and shock was induced. It was inoculated with staphylococci taken from the skin.

Result: The animal died on the second day of general peritonitis.

Experiment XXXVI. Gray rabbit. It was placed upon a hot-water bed; temperature of water in bed, 45° C. It was then inoculated with virulent colon bacilli. The operation lasted for one hour.

Result: The animal died of general peritonitis. Colon bacilli were found.

Experiment XXXVII. Dog. It was placed on a hot-water bed, and the abdomen was opened in a warm room. The viscera were exposed and the animal was inoculated with a mixed culture of bacteria and cocci taken from the skin.

Result: The animal died on the third day.

Experiment XXXVIII. Dog weighing 14 kgm. The viscera were exposed and manipulated. It was inoculated with mixed cultures of colon bacilli from fæces and staphylococci albus and other cocci taken from the skin of a patient before operation. A hot-water bag was placed in the abdominal cavity.

Result: The animal died the following day.

Experiment XXXIX.—Gray-and-white rabbit. The abdominal wall was cleansed as usual and a large median incision was made. Hot-water bags were introduced into the abdominal cavity, beginning with water at temperature 48° C. and raised to 50° C. for forty-five minutes. The stimulation to the viscera was well marked. The peritoneum was inoculated with virulent staphylococcus pyogenes albus. The abdomen was closed and sealed.

Result: No shock, no infection; recovery.

Experiment XL.—Gray rabbit for control. It succumbed under anæsthesia.

Experiment XLI.—White-and-yellow guinea-pig. I opened the abdomen and inserted hot-water bags into the abdominal cavity. Temperature, 48° C., raised to 50° C. Time, forty-five minutes. Evidence of marked stimulation was shown. The animal was inoculated with virulent mixed staphylococcus culture, and the abdomen was closed.

Shock Prevented—Inoculation.

Summary of Tables.

Animals inoculated after shock without heat stimulation applied to the splanchnic area: Dogs, 14; died, 13. Guinea-pigs, 7; died, 6. Rabbits, 4; died, 4
Animals inoculated after application of heat stimulation to splanchnic area to prevent shock: Dogs, 9; died, 2. Rabbits, 4; died, 1. Guinea-pigs, 8; died, 3

Result: No shock or infection; recovery.

Experiment XLII. — Control, black-and-yellow guinea-pig. The abdomen was opened the same as in No. XLI. Stimulation by hot-water bags was omitted. The viscera were exposed for ten minutes. Inoculation was made with staphylococcus, as in No. XLI.

Result: Death. Post-mortem showed acute peritonitis. There were no other marked pathological changes.

In these experiments it is difficult to explain the mode of action of the hot-water bags placed in the abdominal cavity and within the stomach. Heat stimulation thus applied to the splanchnic area for a definite length of time seems to be not only anti-bacterial but also antitoxic in its action. It is not altogether clear whether this result is due simply to the effect of heat acting directly upon the tissues, producing chemical changes, or to the physiological increase in the circulation, or through nerve influence acting upon both tissue cells and circulation. It is evident that blood changes are produced. Experiments seem to indicate that molecular chemical changes are produced—that the "side chains" in the albumin molecule are altered. It is a significant fact that heat applied to the external surface does not result in the same effect produced by heat applied internally.

In connection with the above experiments the following report of surgical cases may be of interest, in which similar precautions were taken against infection and shock:

Case I.—Mrs. J. P.——; operation for carcinoma of the pylorus, a gastro-enterostomy being performed and anastomosis secured by means of the Murphy button. The exposure of the viscera to air was followed by marked congestion of the viscera. In thirty minutes there was apparent collapse. The anæsthesia was withdrawn and artificial respiration attempted, but without resuscitation. A hot-water bag was placed in the stomach, which stimulated respiration, the heart, and circulation. The viscera changed from the bluish shade of congestion to mild hyperæmic tints. The surface grew warm, perspiration appeared upon the forehead and body, and a restoration of the circulation peripherally showed in the return of color to the finger-nails, and signs of shock disappeared. Recovery was complete, the patient leaving the hospital and living for one year afterward.

Case II.—Mrs. McG——, aged forty-five years; hemorrhage from bowels; estimated loss of blood from bowels over one quart. All signs of shock were present, including anæsthesia, disturbance of vision, thirst, cold surface, blue lips; the face wore an anxious expression. The patient experienced a feeling of impending death. The intra-gastric resuscitator (hot-water bag) was introduced into the stomach, and within twenty minutes the symptoms has disappeared, with the exception that the hands and feet were cold; at the end of forty-five minutes these were warm. No other treatment for reduction of shock was used. This was repeated the following day, and the patient felt so well after treatment that she requested a daily treatment, which was instituted for one week.

Case III.—A. C——, aged fifty-two years; gastro-enterostomy and gastrostomy were performed for cancer of the œsophagus, middle portion. The patient was anæsthetized with ether. Upon opening of the abdomen and seizing of the stomach, the patient ceased to breathe. Artificial respiration was employed. While saline solution was being prepared for infusion subcutaneously, three hot-water bags were placed in the abdominal cavity, one in the upper portion near the diaphragm, one in the lower portion, and the third in the side. These stimulated respiration at once. The blue, cyanotic appearance of the patient gave way to natural color. So great was the improvement in his condition that the saline solution, when ready, was not considered necessary, but was held in readiness should signs of collapse reappear. The author's valve operation for gastrostomy was performed, and just before closure of the abdomen the bags were withdrawn.

Result: The patient recovered without shock; the temperature did not rise, and the patient lived six months.

Case IV.—J. I. L——, aged fifty-eight years; carcinoma of the pylorus, atrophic cirrhosis of the liver, and insufficiency of the kidneys. A hot-water bag was placed in the stomach during the entire operation, which lasted one hour and forty-five minutes. No shock was apparent and no infection followed. The patient lived four months.

Case V.—Mrs. W——, aged seventy-two years; operation for benign stenosis of the pylorus. There was also insufficiency of the kidneys. Gastro-enterostomy was performed. A hot-water bag was placed in the abdomen and one in the stomach; temperature of water in the bag in the stomach, 53° C., and of that in the bag in abdomen, 48° C. No shock and no infection followed. The patient lived six months, and subsequently died of uræmia.

Case VI.—William J. K——, agd forty-seven years. Exploratory operation. A large tumor occupying the entire epigastrium and a portion of the umbilical region was found. Diagnosis: Pancreatitis hæmorrhagica and peripancreatitis. The patient went into profound shock with congestion of all the vessels that were exposed; there was anæmia of the surface, and collapse was imminent. A hot-water bag was placed in the stomach, the temperature of the water contained in the bag being 53° C. In fifteen minutes the patient was completely restored from the shock and there was no evidence of collapse; respiration was restored, as were the heart and circulation. The abdomen was closed, and the following day the patient again showed marked symptoms of shock. A hot-water bag was again placed in the stomach at the same temperature as on the previous day, and complete restoration followed. The patient lived one month, and died from the above pathological lesions.

Case VII.—Mrs. M. B——, thirty-six years old; operation for appendicitis and oöphoritis by a prominent gynæcologist. In a preliminary curettage, the uterus was accidentally punctured, and when the abdomen was opened it was found that the fundus was completely lacerated and some of the contents had escaped into the peritoneal cavity. After cleansing away the débris from this accident, an ovariotomy was performed and also an appendectomy. The patient showed marked symptoms of shock; there was marked anæmia of the surface, with very shallow breathing, tachycardia, small and almost imperceptible pulse, and collapse seemed unavoidable. I chanced to be in the hospital at the time the operation was going on, and was called in to resuscitate the patient. Placing a rubber bag with a double tube in the stomach, I introduced water into the bag at a temperature of 53° C. This was allowed to remain in the stomach, and a continuous current was kept playing through the bag, about 500 c.c. of water remaining in the bag all the time, for about one-half hour. This resulted in a complete restoration from shock and collapse. The following morning the patient exhibited signs of shock, and I was again called and carried out a similar procedure. At the end of twenty-five minutes there was complete restoration, and from this time the patient made an uneventful recovery, without shock or infection.

Case VIII.—J. J. S——, aged forty-one years; operation upon the cystic duct; operator Dr. Newman. A case of atrophic cirrhosis of the liver, and atrophic gall bladder. The gall bladder was opened, the stone removed, and the wound packed. Shock was present,

but reduced by the use of a hot-water bag in the stomach. The patient died on the fourth day, of shock or infection, or both.

Case IX.—Mrs. B. A. C——, aged forty-three years; chronic enteritis of seven years' standing, and contracted liver. I opened the abdomen and placed hot-water bags in the abdominal cavity and also introduced one into the stomach. The gall bladder was drained for four weeks. The patient suffered no shock or infection or signs of exhaustion from the operation. She completely recovered.

Case X.—E. J. K——, aged forty-eight years; referred by Dr. Beveridge of South Dakota. She suffered from benign stenosis of the pylorus, resulting from cicatricial ulcer. There was an immense dilatation occupying the epigastric and umbilical regions and the great curvature reaching into the hypogastric region. The patient weighed but one hundred and four pounds, having lost sixty-eight pounds since the illness began, and was very weak, stenosis of the pylorus being complete. Hot-water bags were placed in both the abdominal cavity and the stomach, and a gastro-enterostomy performed. In this patient, a rubber dam was placed over the abdominal opening and one spread over the abdomen below the wound to prevent infection. The stomach was drawn through a small aperture in the rubber dam and a loop of the jejunum drawn through another small aperture in the rubber dam. This was done for the purpose of preventing any escape of stomach contents into the abdominal cavity, and also to prevent hemorrhage by the constriction of the viscera drawn through the small apertures. Anastomosis was made by a double row of sutures. The rubber dam was then cut, and the viscera were freed and replaced in the abdominal cavity, and the wound was sutured. There was no shock following the operation and no apparent exhaustion. The patient was fed the following day and continued to improve, to gain in weight, and was discharged in four weeks. At the last report, two years and one month since operation, the patient had gained in weight (60 lb.) and strength and continued his work regularly on the farm.

Case XI.—I. J. H——; operation for stenosis following duodenal ulcer in the first portion of the duodenum, just beyond the pylorus; periduodenitis, with adhesions. Hot-water bags were placed in the abdominal cavity after being opened and rubber dams adjusted, as in Case X. The stomach was drawn through an aperture in the rubber, and the intestines were drawn through another slit. Gastro-enterostomy was done, with anterior suture. The operation lasted one hour and twenty-five minutes. Hot-water bags were changed at intervals, keeping the temperature of the water at 48° C. There were no infection and no shock. The patient was fed the following day, and he made an uneventful recovery.

Case XII.—J. G. T——, aged forty-four years; stenosis of the pylorus with gastric dilatation. Gastro-enterostomy was performed. Hot-water bags were placed in the stomach and also in the abdominal cavity. The operation lasted one hour and fifteen minutes. The patient recovered.

Case XIII.—J. G. F——, aged fifty-one years, complained of gastric disturbance, icterus, and general emaciation. Examination showed a contracted liver, contraction of the stomach, insufficiency of the kidney, and general fibrosis. The operation was exploratory. A contracted gall bladder was found, which was opened for drainage.

Result: The patient died on the fourth day. Death was the result of "exhaustion," probably infection.

Case XIV.—Mrs. B. A. J——, aged thirty-one years, complained of constant vomiting and occasionally vomited small quantities of blood; she also complained of icterus. The liver area was contracted and the urine contained albumin. The stomach was markedly contracted. Preparation for the operation was made in the usual manner and the incision made, after which the rubber protectors were adjusted, hot-water bags having been placed in the abdominal cavity. The gall bladder was distended and the rubber shield pulled around it. The gall bladder was then opened and exploration for stone made, which proved negative. The gall bladder was then sutured. During the operation, the bags in the cavity were changed frequently. The abdomen was then closed, but drainage of the gall bladder was continued for four weeks. The patient made an uneventful recovery.

Case XV.—Mrs. J. L——, forty-one years old, presented condition of cicatricial stenosis in the rectum, due to an ulcer. During the operation, the patient went into collapse, following apparent shock. I introduced a hot-water bag into the stomach at a temperature of 53° C. This resulted in resuscitation after five minutes, and the operation was completed. The patient made an uneventful recovery.

Case XVI.—Mrs. P. McC——, thirty-nine years old, suffered from chronic diarrhœa, with blood discharges. Examination of the fæces showed tubercle bacilli. Upon opening of the abdomen, tubercle infection of the ileum and a small portion of the ascending colon was revealed. Hot-water bags were placed in the abdominal cavity. A part of the ileum, the cæcum, and a portion of the ascending colon were drawn through apertures in the rubber protector and a resection was made, with anastomosis between the ileum and colon. The patient experienced no shock and no secondary infection, and was discharged from the hospital five weeks later, apparently much improved.

Case XVII.—F. L. R——, thirty-six years old, complained of frequent vomiting and emaciation. Examination showed dilatation of the stomach with obstruction. The usual aseptic precautions were taken; the abdomen was opened, hot-water bags were placed in the abdominal cavity, and the rubber protector was adjusted. Examination showed cicatrical stenosis just beyond the pylorus. Gastro-enterostomy was decided upon. The stomach and intestine were drawn through slits in the abdominal protector; the stomach was opened and the mucous membrane everted. A long longitudinal incision was made in the intestine. The stomach was invaginated into this large opening in the intestine, and the intestine sutured transversely to the long axis of the bowel, making the intestinal opening of sufficient size to accommodate the stomach. The remaining portion of the intestinal incision was sutured in the following manner: At the upper extremity of the everted mucosa, the intestine and stomach were united by two rows of sutures, the first including the intestine, the everted portion of the stomach, and the serous coat of the stomach. The second row was the ordinary Lembert stitch, thus causing sero-serous apposition, the everted mucosa of the stomach acting similar to the ileo-cæcal valve. This large opening prevented stenosis or spur, the valve preventing regurgitation and the everted portion preventing closure of the gastric opening. From this operation there resulted no shock, no infection, and no vomiting. The patient made an uninterrupted recovery; he was able to take liquid food the following day and was given chopped meat on the fifth day.

Case XVIII.—J. B. P——, fifty-one years old; carcinoma of the œsophagus; alcoholic for twenty-five years, atrophic cirrhosis of the liver and interstitial nephritis. I opened the abdomen and introduced hot-water bags in the abdominal cavity. Temperature of the water in the bags was 48° C. Turck's valve gastro-enterostomy was performed. Before the complete sutur-

ing of the stomach to the peritoneal wall, the bags were withdrawn through a small aperture. The operation covered one hour and fifteen minutes. There were no shock, no infection, and no evidence of exhaustion following the operation. The patient was fed at once through the fistulous opening. Seven months after operation he was still alive.

Conclusions.—I. Pathogenic and non-pathogenic bacteria, found on and in the skin before and during surgical operations, may produce infection.

II. The skin, especially in abdominal operations, is a source of infection that may cause death, though all usual precautions are particularly taken. Susceptibility to infection is produced in cases of lowered vitality and weakened condition; or in cases in which shock is present, from whatever cause, in a mild or severe form.

III. The present methods yet in use, of towels and laparotomy sheets, do not sufficiently protect the field of operation.

IV. The use of the rubber protector which is made to fit close to the skin more thoroughly prevents the danger of infection from the skin, and also lessens the liability of the skin becoming contaminated from the escape of visceral contents, pus, or other infected material occurring during the operation.

V. The peritoneum may become infected from the escape of visceral contents or from any infected cavity opened during surgical operations in the abdomen. Infection may result, even after the most careful precautions are taken, notwithstanding the use of gauze and careful packing, now in common use.

VI. When death occurs from supposed "shock" or "exhaustion," especially when the viscera have been exposed to dangers of infection by the escape of visceral contents, the death is probably due more to the infection than to "shock" or "exhaustion."

VII. Whenever practicable, the viscera may be drawn through the small openings of the protective rubber shield overlapping the abdominal wound, as described in this paper, and absolute protection to the abdominal cavity is secured.

VIII. Exposed viscera may be covered with a rubber hood, kept warm by small rubber hot-water bags, thus preventing contamination as well as lessening susceptibility to infection.

IX. Animals naturally immune to certain bacteria are rendered susceptible by exposure of the viscera to air for one hour or more.

X. Susceptibility can also be produced in an animal naturally immune, by long manipulation of the abdominal viscera, notwithstanding all ordinary precautions are taken. Visible trauma is not essential.

XI. In animals in which susceptiblity is not artificially produced, only slight effects are observed after intraperitoneal inoculation of microorganisms taken from the skin before surgical operations.

XII. When an animal is rendered susceptible by exposure of the viscera to air, pathogenic and many non-pathogenic micro-organisms inoculated may cause infection followed by death.

XIII. Subcutaneous or intravenous infusion of physiological salt solution does not materially render the animal less susceptible, after the exposure and manipulation of the viscera.

XIV. When heat at 48° or 50° C. is applied within the abdominal cavity during the time corresponding to the exposure and manipulation of the viscera (about one hour), inoculation by pathogenic or non-pathogenic germs seldom results in infection and death.

XV. If infection does occur, death is delayed, or seems prevented, as a result of the procedure described. Susceptibility to infection is not materially decreased by the external application of heat.

XVI. Hot-water bags placed in the abdominal cavity during an operation prevent shock or collapse, and also produce a modified immunity or lessen the susceptibility to infection.

XVII. In severe operations, when extreme shock or collapse is present, resuscitation is best accomplished by the application of heat within the stomach and abdominal cavity, by the methods already described.

AFTER-PAINS FROM EXTRACTION OF TEETH.

By CHARLES B. ISAACSON, M.D.,

NEW YORK.

THERE is no condition which is brought oftener to the attention of the medical practitioner than what is called "after-pains" from extraction. There is no subject in dentistry which has been touched upon less, or to which so little special attention has been given, than this condition. Here and there, in a desultory way, suggestions of methods and remedies have been made, but in all of them, as far as my research goes, there has never been any direct attempt to fathom the causes and to approach the condition radically.

This condition of after-pains generally arises one or two days, or even a week, after the offending member has been extracted. The symptoms vary in intensity from causes which I shall proceed to enumerate.

The average practitioner, when called upon to relieve patients suffering with after-pains, or as the Germans call it, "Zahnlückenschmerz," is generally puzzled how to proceed, not knowing the exact nature of the condition presented to him, the appearance being so unusual, the swelling so intense, with undoubted signs, in a large majority of cases, of pus burrowing under and through the tissues, that the first impression is the indefinite expression "blood poisoning," which in ninety-nine cases I look upon as a snapshot diagnosis.

The direct physico-pathological causes are dimly recognized, and relief is sought by the usual antiseptic measures, which, in minor insignificant cases, may be successful.

The local application of cocaine in solution to highly inflamed tissues I hold to be reprehensible; for tissues in that condition do not absorb the medicament, and the danger of a harmful quantity of the drug being swallowed is great. Again, I cannot deprecate too strongly what I may call the wanton use of hot poultices on the face; it seems as if the intervening thickness of the facial muscles is entirely ignored, while the result obtained is only the further infiltration of pus, and the extension of the inflammation to tissues which had been entirely normal, thus causing the original trouble to be exacerbated.

In some cases it may be necessary to use heat in order to lessen the tension, but surely it is only logical to apply the heat directly to the parts affected, which can be very easily done by using pledgets of cotton or pieces of gauze, folded to a sufficient size, steeped in hot water (one or two per cent. solution of carbolic acid is suggested) or a hot infusion of chamomile flowers. The heat is thus applied directly where it is wanted. I have always found cold packs contraindicated.

I wish to enumerate the possible causes of after-pains, and at the same time venture to suggest the means of relieving the same: (1) the retention of the pyogenic membrane in the socket; (2) expansion of the osseous walls; (3) fracture of the alveolus; (4) sundering of the maxillary process and alveolus, with accompanying lacerations of the tissues; (5) the retention of roots and spicula in the socket; (6) that

particular condition of the alveolus and septum from which the gum tissues have been denuded by the encroaching of salivary calculi; (7) the inflammation of the tissues and the undermining of the alveolus from perforation by pus from long-standing pyorrhœal discharges or alveolar abscesses from old roots.

1. The retention of the pyogenic membrane is generally followed by acute pain. When a tooth with septic pericementitis is extracted, the pericementum may or may not be attached to the root. As there is an intense inflammation with plastic exudations, the chances are that the pericementum will still adhere to the lining membrane. In order to relieve this condition, it is necessary to remove all clots, and to curette the socket. For this a small, blunt curette, or preferably a rose burr in the dental engine, should be used. As a soothing application, I have found the following prescription very effectual, used on a tampon in the socket:

℞ Mentholi,
Acidi carbolici,
Tinct. iodi.....āā ʒi.
Ether.,
Chloroform.....āā ʒss.
M. S. External use.

Of course, after the curetting it is necessary to irrigate the socket with a solution of hydrogen peroxide, plus any antiseptic, optional with the practitioner.

2. The expansion of the osseous walls. This condition will require careful examination, and is usually met with when the tooth has been difficult to extract on account of the unyielding walls, and is generally most noticeable when the lower wisdom teeth have to be excised from the thickened alveolus. In a large number of these cases, the outer or the inner wall has been bent, and possibly slightly fractured. In many such cases I have found the usual methods of irrigating and packing of little or no avail. The suffering is usually intense, while the swelling interferes with deglutition, and the pocket becomes a veritable receptaculum for mucus, food, and unhealthy granulations. In these cases I have managed to obtain relief in a very short time by using the rose burr and cutting away the bent ridge, burring away all the irregular edges, making the parts as smooth as possible. This is to be followed by irrigating and packing, and, I believe, with signal success. In minor cases, in which the alveolus has been bent out of shape, compression of the parts, with thorough cleansing of the cavity, will answer. I have always been suspicious of cases in which the alveolus has been luxated, and always feel more confident when I have removed that part.

3. Fracture of the alveolus. This would require the removal of the fractured part, smoothing of all the irregular points, the usual thorough irrigation and antiseptic treatment.

4. Sundering of the maxillary process and alveolus, together with laceration of tissues. This will present to the practitioner the appearance of a large surface, intensely inflamed, caused by the gum contracting over the serrated edges (for, like all tissues, the gum forms a cicatrix, which exerts considerable pressure). The gum, in trying to contract over these sharp points, becomes intensely inflamed, the pus burrows underneath, forming pockets along the whole ridge, and owing to the sack-like condition is generally in a septic condition.

The treatment in this case is to relieve the condition by one or more incisions parallel to the axis of the maxillary; then with the curette, or still better with the burr, all irregularities of the alveolus and maxillary should be cut away, so that the surface is absolutely smooth. A thorough irrigation of the parts and packing them with antiseptic gauze will bring about desired results. In deeper cavities I have used almost every remedy recommended, but have found that none possessed the analgesic properties of iodoform, and though this is so objectionable by reason of its odor, it seems to do its work.

5. When there is retention of the root, and spicula are in the pocket, the cavity is to be cleansed of the spicula; and if the root cannot be removed by forceps or is too small to be grasped, it can be burred out.

6. This condition is a peculiar one, but easily recognized and diagnosticated. This occurs mostly with teeth which have become elongated from want of antagonism; the roots are more or less exposed; deposits take place on them, pushing the tissues farther up from the alveolar wall, leaving it and the septum denuded. After extraction (these teeth are often pulled out by the patient himself), the gum refuses to cover the necrotic wall and septum—hence painful consequences follow.

Relief in this case is very easily obtained by cutting away the dry, friable, necrotic bone until the healthy bone is reached. The usual antiseptic treatment and irrigation are in order.

7. Perforation of the alveolus from an invasion of pus. When repeated perforations have taken place in the alveolar wall, it may be assumed that the nutrition of this bone has been largely interfered with, impaired, or arrested, and that the wall thus undermined really becomes a sequestrum. The appearance of such a condition would be a large pocket, a bulla of pus outside the ridge, considerable swelling, and possibly the burrowing of pus in several directions. This condition, I have noticed in a large number of cases, takes place long after extraction. The treatment for the same would be a crucial incision, removal of the necrotic wall or sequestrum, and a smoothing of the parts, irrigation and packing as in the preceding cases.

As these cases come under the observation of physicians who are called in to correct the blood-poisoning, which the patient is always supposed to have, and as a great deal of censure is given to the dentist for having extracted the tooth so brutally or so unskilfully, I wish to say that I have sufficient respect for the ability of my confrères to know that these conditions are never produced intentionally, and that they are due to causes which may be beyond their ken, and which arise unexpectedly. Much may be ascribed to the neglect of the patient. The medical practitioner, not being familiar with the mouth, resorts to general antiseptic treatment, whereas these conditions, as before mentioned, can be known only to the dental practitioner and oral surgeon, and should be handed over to the dental practitioner instead of worrying the patient with a long course of treatment, futile in the end and generally accompanied by a liberal dose of opium.

In performing these operations, I have found it more advisable to do so by the aid of ethylic chloride or the injection of cocaine. The use of nitrous-oxide anæsthesia I have found impracticable on account of its short duration and the danger of using the dental burr in a hurry. Of course, in some cases, anæsthesia by ether or chloroform is absolutely necessary to perform the operation thoroughly.

I have not mentioned the possible inoculation from unclean instruments. Such cases have to be diagnosticated *per se*. I have omitted to mention the pains which may, and often do, arise in neurasthenic patients; pains which persist in syphilitic patients; and finally the vagaries of the female nervous system during pregnancy and the catamenia. These require the careful attention of the medical practitioner for constitutional treatment, with the advisable collaboration of a dental surgeon. Every practitioner fastens

upon some remedy which has proved faithful to him; so the selection of any preparation, from mercuric bichloride down to boric acid and formalin solutions, is purely optional.

To conclude, I wish to convey the idea that such pains are caused only by foreign substances, whether they are spicula, sequestra, tissue, clots, mucus, or food retained in the socket; and the removal of these is paramount in any local treatment that can be used.

101 East Sixtieth Street.

A New Method of Catheterization of the Eustachian Tube.—G. Ostino, noting that when the letter "e" is pronounced the soft palate raises itself and the Eustachian cushion approaches the median line, suggests the following method: A mark is made on the curve of the catheter 7 cm. from its tip. The catheter is then passed in the usual manner until the mark is opposite the entrance of the nose, this distance of 7 cm. being the average distance between the anterior and posterior nares. The patient then phonates "e" (English) in a continuous tone, at which moment the catheter is rotated externally. Ostino claims that this manœuvre will positively engage the tip of the catheter in the pharyngeal orifice of the tube.—*Archivo Italiano di Otologia*, etc., x., 1, 1900.

Curable Forms of Hydrophobia in Man.—G. Daddi reports the case of a young surgeon who was bitten by a dog in the left popliteal region; the wounds were not deep, and were cauterized with pure ammonia. The patient came to the Anti-hydrophobic Institute in Florence for treatment merely as a precautionary measure, being firmly convinced that the dog was not mad. An examination of the dog's head proved that it had rabies, but the patient was kept in ignorance of the fact. He developed fever, paralysis of the detrusor urinæ, paraplegia with abolition of patellar reflexes, and pains in the lower limbs; but the symptoms finally subsided, and complete recovery ensued. By a process of exclusion, the author comes to the conclusion that the complex of symptoms was due to inoculation with the virus from a rabid dog.—*Rivista Critica di Clinica Medica*, June 30, 1900.

Colic Pains.—Lucke analyzes the various possibilities involved in the etiology of colic, concluding that the painful seizure is always the result of tension, and that muscular spasm, though often a predisposing or aggravating factor, is not, as usually thought, to be considered the prime cause. When the increase in pressure is so gradual that dilatation can keep pace with it, no colic results, as is true of the cases of painless hydrops of the gall bladder; when the stoppage is sudden, however, as when it is due to an impacted gall stone, the pressure rises rapidly and the tension produces severe pain. Intestinal colic and the pain due to impaction of a renal calculus in the ureter are explicable on the same grounds. Pure renal colic unaccompanied by the existence of stones is due to an intense and sudden congestion.—*Wiener klinische Wochenschrift*, July 5, 1900.

The Roentgen Rays in Diseases of the Nose, Throat, and Neighboring Organs.—John MacIntyre, who has done more work in this special direction than any one else, makes a strong plea for the systematic examination of cases with the *x*-rays in order to obtain accurate information as to the relative value of these and other methods of diagnosis. In the majority of cases of traumatic lesions, aneurism, malignant disease, glandular enlargement, fluid effusions, deposits in the lung, etc., other signs are, as a rule, present, and the shadows obtained by the *x*-rays have, therefore, only a place among the different aids to diagnosis; but in a minority of cases he has been able to obtain by the rays information which otherwise could not have been obtained. He believes that in the hard tissues we may profitably use the rays in the study of the anatomy of the nose, antrum, and spine, and may detect fractures and injuries of the nose and maxillary walls and tumors. In the soft tissues we may be able to make out cardiac enlargement, transposition of the viscera, mediastinal gland enlargement, malignant and other neoplasms of the jaw and chest, abscesses, collections of fluid in the chest, deposits in the lung, etc. Moreover, we can ascertain the presence of foreign bodies in the antrum, nose, pharynx, upper-air tract generally, and in the œsophagus.—*Journal of Laryngology*, July, 1900.

A Case of Acetanilid Habit.—G. W. Gaines writes that some four years ago acetanilid was prescribed for a negro adult suffering from rheumatism. He found that he was relieved by its administration, but on leaving off the medicine for a few days the pain returned. So he began taking it constantly each day. Now he uses two ounces each week and has been doing this for some months. It is not stated whether the man suffers any ill effects of his habit.—*New Orleans Medical and Surgical Journal*, July, 1900.

Abscess of the Cerebellum.—M. Dieulafoy describes a case with the details of the post-mortem findings. Abscess of the cerebrellum is nearly always due to otitis. The symptoms which it causes are occipital headache, vertigo, ictus, loss of equilibrium, titubation, vomiting, nystagmus, cervical contracture, optic neuritis, muscular asthenia, somnolence, torpor closely allied to coma. Facial paralysis and paralysis of the external oculomotor nerve may occur, as in the case described. In abscess of the cerebrum the motor disorders, the paresis, contractures, and spasms are on the side opposite to the lesion and to the otitis, and word-blindness and hemianopsia further constitute the differential diagnosis. Tumors of the cerebellum, as glioma, gliosarcoma, etc., give the same complex of symptoms, but rarely in so simple a form, as their tendency to invade surrounding parts causes the addition of other symptoms. Surgical intervention is the only form of treatment possible in cases of cerebellar abscess.—*Bulletin de l'Académie de Médecine*, June 26, 1900.

The Varicose Osteo-Hypertrophic Nævus.—Klipper and Trenaunay under this title describe a congeries of symptoms which they consider sufficiently constant to be grouped as a specific disease. In the light of their own observations and of many cases culled from the literature, they would establish the following as the characteristic tripos of the symptomatology: (1) A nævus covering the lower extremity and metameric in its distribution; (2) varicosities limited to the diseased side and congenital, or dating from early infancy; (3) hypertrophy of all the tissues of the diseased side, but involving particularly the bony structures, which are increased in length, breadth, and thickness. In addition to these there are many other less important and more variable lesions. The skin may be wrinkled and dry, show scars of old ulcers, or be covered with desquamating patches resembling ichthyosis; sometimes elephantiasis is a complication, or the cutaneous surface may be indurated and scaly. The hair is usually absent in the neighborhood of the nævus. The nails are striated, brittle, and deformed. Hyperidrosis may exist, and frequently the deformity is increased by the hypertrophy of the cellular and fatty tissue, which may produce more or less circumscribed tumors.—*Archives Générales de Médecine*, June, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 11, 1900.

ANTITYPHOID INOCULATION.

THE question as to whether inoculation against typhoid fever is a successful means of either prevention or cure, or of both, is of the utmost importance to this country as well as to almost all the countries of Europe in the present unfortunate combination of events in the Far East. China is a land in which sanitation is at a notoriously low ebb, and whose inhabitants wholly disregard the ordinary laws of hygiene as understood by Western people. This being so, judging from the experience gained in former wars, disease will doubtless figure more largely in the death roll among the troops engaged in the task of bringing about order in the Celestial Empire than will injuries produced by shot and shell.

Of all the maladies which strike down the soldier in the field none claims so large a share of victims as does enteric fever. This is a truism. Even in lands where sanitation is carried out in a more or less effective manner, there have as yet been discovered no absolutely sure methods of preventing this disease or of staying its spread when it has once broken out and has gained headway among a large body of men. This fact was plainly demonstrated in the military camps formed in this country during our war with Spain. It is true that typhoid fever is classed as a preventable disease, but it is an extremely difficult matter to prevent it under all the conditions of war, and infinitely more difficult to check its ravages when its germs are being disseminated within the confines of a camp.

Undoubtedly strict sanitary supervision and care will go far toward preventing an outbreak of this disease and toward nipping in the bud a threatened epidemic. But when all has been said that is to be said on the subject, it must be acknowledged that much yet remains to be learned concerning the etiology and the most effective mode of fighting and controlling the disease. It is therefore—and especially in view of the crisis in China—with feelings of the liveliest and most serious interest that the reports of the results of the serum treatment of enteric fever, to which many British soldiers now in South Africa were subjected, are being watched by scientific and medical men throughout the world. Although inoculation against typhoid fever has been practised in the British army in India for a few years, and although Professor Haffkine declares that it has been successful in reducing the mortality there to a very large extent, the statistics to hand are not sufficiently convincing altogether to uphold this statement, and the method may to all intents and purposes be said to be now on its trial. Opinions of the medical men serving with the British army in South Africa are conflicting. Sir William MacCormac says: "No decided opinion can yet be given on this point, since there are no sufficient data for statistics. The observations made seem to show that those inoculated are less apt to take the disease, or if they are attacked they have it in a milder form; but the question is still *sub judice*." Dr. Conan Doyle writes in the most eulogistic strain in regard to the immunizing or rather the protective properties of the serum. He says: "There is one mistake we have made which I think will not be repeated in any subsequent campaign. Inoculation for enteric fever was not made compulsory. If it had been so I believe that we should (and, what is more important, the army would) have escaped from most of its troubles. No doubt the matter will be fully threshed out in statistics, but our strong impression from our own experience is that although it is by no means an absolute preventive it certainly modifies the course of the disease very materially." Surgeon-General Jameson, as was mentioned in the MEDICAL RECORD of July 21st, does not seem to be very enthusiastic in respect to antityphoid serum as an immunizing agent, although he naturally speaks in somewhat guarded terms.

A correspondent of the *Lancet* from the front gives his views as follows: "At present it is perhaps too early to condemn inoculation against typhoid fever. It certainly does not prevent a person from contracting the disease, and it seems doubtful whether the inoculated person will show any greater immunity than the non-inoculated person. Slight attacks have occurred in both classes of patients, and two in this hospital have succumbed to the disease. On *a priori* grounds one would hardly expect that a preventive-serum treatment would be successful in a disease which, after it has existed for something like three weeks, cannot protect a person from a relapse. Moreover, second attacks are by no means unknown, and one patient had a most severe second attack of typhoid fever from which he died; so that a previous attack does not seem either to protect from the disease or to lessen its severity."

Again, to judge from the statistics relating to the action of the serum during the siege of Ladysmith, the conclusion one would arrive at is that, while inoculation affords a measure of protection from attack, those inoculated suffer more severely when seized with enteric fever than those not inoculated. Nevertheless, if Dr. Conan Doyle and others are right in claiming for antityphoid inoculation protective properties however modified, a most valuable discovery has been surely made. Further and more accurate statistics from Africa will be needed to elucidate the matter, and until that time no decided opinion regarding the value of the serum can be formulated.

FISTULA AFTER OPERATIONS FOR APPENDICITIS.

When a fistula, with mucous or fecal discharge, persists after an operation for appendicitis we have to deal with a situation always awkward for us, and uncomfortable or dangerous for the patient. We know that a fistula is most likely to result in those cases in which, in the presence of suppuration and necrosis of tissue, operation is deferred, and least likely to occur in cases in which the appendix is removed while the inflammatory process is confined to the interior of that organ, and the wall of the cæcum is in healthy condition. This gives us a good idea of some of the local conditions which are followed by fistula, and enables us to lay down rules which do not favor delay in the operative treatment of the disease.

When we find the cæcum swollen and œdematous, with purplish or even black or dark-green spots in its wall in the neighborhood of a more or less gangrenous and sloughing appendix, we know that a fistula is not infrequently the sequel, and we also know that the local conditions mentioned are seen in those cases in which operative intervention has been delayed beyond safe limits. Some of these fistulæ heal spontaneously after longer or shorter intervals even when they are left severely alone, and others pursue a course of extreme vexation to patient and surgeon. The best treatment for them does not seem to be settled, if we can judge by a recent discussion at the meeting of the American Medical Association, but there is certainly no doubt that the only cure is by operation, which is, however, attended with considerable mortality. Some fistulæ appear as practically straight tracts lined with granulation tissue and leading to the cæcum at or near the original insertion of the appendix. Such fistulæ will at various times discharge mucus, gas, pus, or fecal matter in varying proportions. In addition to straight fistulæ like these, there may also be present various degrees of tortuosity and complexity, and there may be branches running into various parts of the iliac and pelvic connective tissue which can add considerably to the difficulty of an attempt at operative cure.

We may also sometimes see fistulæ which are caused by the presence of a larger or smaller remnant of the appendix with its mucous membrane, which goes on secreting and thus furnishes the discharge. This sort of fistula is apt to be most amenable to the milder forms of surgical work, but is not likely to undergo a permanent spontaneous cure. The chances of spontaneous cure in the other form is not great if the condition has shown that it will not heal within eight or ten weeks from the operation for the acute disease, and something of a radical nature will probably have to be done. The operation which will be found to give the best results is one started as an exploration following the tract, and developing its sinuosities and general character, and then proceeding as conditions demand. If we arrive in this way at the cæcal wall and find a more or less ragged opening through it, without much change in the iliac connective tissue, or even if there is considerable, a suture may be successful In order to be so, however, it must be done with great exactness, and we must remember that we have no longer the advantage offered by the quick adhesion of fresh peritoneum to depend upon, but that we are working in more or less refractory connective and muscular tissue. The sutures should be applied as is done in the case of wounds of the bladder, and it seems a good plan to treat the more superficial parts of the wound to some extent at least by the open method. Great care is necessary to prevent some of the secondary tracts from escaping our attention. If some such attempt, perhaps necessarily repeated, is made in these cases of fistula, it will probably very rarely be necessary to perform the much more serious operation of intestinal resection, which is decidedly not free from risk.

SATURNINE INTOXICATION THROUGH THE USE OF LEAD OINTMENT.

Too much emphasis cannot be laid on the injunction, in the treatment of a given condition, to seek the cause and direct therapeutic measures against it, although it is appreciated that it is necessary at times to give consideration to individual symptoms. Thus, in the treatment of anæmia or of glottic spasm or of convulsions, it is of the utmost importance to determine the underlying factors, for unless these are removed a permanent curative result cannot be hoped for. The convulsive seizure that sometimes attends the onset of acute febrile disorders can scarcely be looked upon as a physiological manifestation: else it would be more common than it is. Under such circumstances a careful study of the family history may reveal some predisposing influence. When the tendency to convulsions is thus well defined it may sometimes be counteracted by the timely administration of a sedative, such as the bromides. If, for instance, it is known that a child is generally seized with convulsions as a result of febrile disturbance, the attack may often be aborted by prompt treatment with bromides at the time. Less is certainly to be feared from this sporadic administration of the sedative than from the convulsive seizures themselves.

A febrile convulsion may be epileptic or uræmic or due to auto-intoxication, or possibly to poisons introduced from without. Some observations bearing upon the last-named mode of origin are recorded by Hahn (*Archiv für Kinderheilkunde*, B. 28, H. 3 u. 4, 1900), who briefly records two cases in children under treatment for eczema of the scalp with lead ointment, in which convulsions occurred and saturnine intoxication was suspected, and a third case of similar kind, also attended with convulsions, in which death resulted and the existence of plumbism was determined chemically. This last case occurred in a child nine months old, presenting an old and neglected eczema of the face and head, for the relief of which an ointment containing lead oxide was prescribed, the mother being carefully instructed to return at short intervals. This injunction was, however, not obeyed, and after the lapse of four months the little patient was found in convulsions, without fever and with a hard, running

pulse. In spite of removal of the ointment, the application of sulphur, and the administration of bromides, the convulsive attack was repeated, and the child subsequently became comatose. A dark line was found on the gums around one of the teeth. The fontanelle was bulging; the knee jerks were increased; the eye-grounds were normal. The urine contained a trace of albumin, and uric acid in large amounts. Lumbar puncture was performed, and 20 c.c. of clear fluid permitted to escape. The child, however, failed to rally, and death resulted. Histological examination failed to disclose any degeneration of the ganglion cells of the cerebral cortex, and chemical examination revealed the presence of lead in the brain tissue. It is pointed out that the diagnosis in this case might have been overlooked if it had not so happened that the condition was being eagerly searched for. The convulsions were not distinctive, and the subsequent coma might have been due to uræmia or to persistent cerebral pressure. Uræmia was, however, excluded by the results of examination of the urine, and a number of cerebral disorders by the results of lumbar puncture.

THE THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

The Paris Congress, a full report of which, cabled by the special correspondents of the Medical Record, is presented to our readers in this issue, will undoubtedly be looked back upon as one of the more notable of this series of international gatherings—notable for its numerous attendance if not for its scientific importance. The attraction of the *fin-de-siècle* Exposition doubtless drew many whose scientific ardor might not otherwise have impelled them to travel so far to take part in a purely medical meeting. The large attendance of the Germans sufficed to offset the absence of the English, who were kept away partly because of the not very cordial political relations between France and their country, and also by the fact that the meeting of the British Medical Association at Ipswich was held at the same time. The Americans were in greater force than at any previous international medical congress, except, of course, the one at Washington, and they were not only present but took a prominent part in the proceedings of several of the sections. Dr. Jacobi, in his well-meant though rather unnecessarily apologetic address, presented the claims of American medicine to recognition by the world at large; but if the physicians and surgeons of the United States will speak for themselves at future congresses as they did at this, there will hereafter be no more need of apologists for American medicine than there is now, we take the liberty of reminding our eminent fellow-citizen, of apologists for American politics. Full as is our special report of the scientific work of the congress, it is impossible to judge from it of the real importance of the work done at Paris, and it will be necessary to wait for the more complete mail reports in order to form a just estimate of the congress on its scientific side. That it would be a success socially was a foregone conclusion. The Frenchman as a host is unapproachable.

News of the Week.

Sanitary Reforms in Manila.—Dr. J. J. Curry, recently in the Philippines, is reported in an interview on the health conditions of the islands as follows: "The hygienic conditions are greatly improved. The board of health has made a new city of Manila. The people seemed to know nothing of sanitary laws, and did not know what sanitation meant. The lepers have been rounded up, and are kept in a large roomy hospital with spacious grounds, which was formerly a convent. A tent quarantine has been established for plague and other diseases. Native and Chinese inspectors have charge of their respective quarters, and have done efficient work. The general condition of the troops is very good, considering their hard work and long marches. The supplies, both food and medical, are plentiful, even in the interior, although they have to be drawn for miles and miles in bull carts. Hospitals are established all over the islands and in every garrison town. In the larger hospitals there are trained women nurses in addition to the hospital-corps men. The convalescent hospital at Corregidor Island is a splendid institution, beautifully situated on the crest of a hill, where it receives the cool breezes of the China Sea."

Erratum.—In a report of the meeting of the American Association of Genito-Urinary Surgeons, published last May, Dr. Chismore was credited with recommending a particular preparation of urotropin. He writes that he was incorrectly reported, not having recommended the preparation in question, but having inquired what the experience of others with it had been.

Yellow Fever.—Several cases of this disease were discovered on August 2d at Tampa, Fla., which are supposed to have been imported from Cuba. On August 3d Dr. Weedon, of the State board of health, issued a statement announcing that there had been one death there from yellow fever, and that there were two other cases known to exist in the city at that time. In Havana, despite stringent sanitary precautions, yellow fever is now on the increase, fifty cases being under treatment on Tuesday of this week. The mortality has been thus far usually low. This disease is also reported to be on the increase in Pinar del Rio. The Louisiana board of health decided on August 2d to enforce a quarantine of five days against all Central American fruit vessels carrying passengers. The Louisiana inspector at Port Limon, Costa Rica, has reported several cases of suspicious fever and one of acknowledged yellow fever, and it is believed the board has information of the presence of the disease at others of the Central American ports. The United States Consul at Progreso, Mexico, reports that yellow fever in malignant form prevails at Merida, Yucatan, and that the epidemic is spreading.

Dr. S. A. Knopf, of this city, has received the international prize of 4,000 marks offered by the Berlin Tuberculosis Congress for the best popular essay on

"Tuberculosis as a Disease of the Masses and How to Combat it." The committee of award was composed of some of the best-known clinicians and sanitarians of Germany, among them being Leyden, B. Fränkel, Gerhardt and Leuthold. There were eighty-one competitors. According to the terms of the competition, the German committee for the erection of sanatoria for the tuberculous will publish the essay in a cheap form for popular distribution. Dr. Knopf already enjoys a wide reputation as a worker in this field, and to him was awarded in 1898 the Alvarenga prize of the College of Physicians of Philadelphia for an essay on "Pulmonary Tuberculosis, its Modern Prophylaxis and Treatment in Special Institutions and at Home."

Dr. G. E. Morrison, the Peking correspondent of the London *Times*, is a physician who received his medical education in Melbourne and London. He is thirty-six years old and an Australian by birth.

An Ambulance Wrecked.—An ambulance of the Harlem Hospital, in which were seated Dr. Levy and the driver, was struck by a trolley car of the Second Avenue line on Saturday. The ambulance was thrown against an elevated railroad pillar and badly wrecked. Dr. Levy was thrown out and received some injury.

The Physicians of Lake Keuka.—The second annual meeting of the physicians of the Lake Keuka (N. Y.) region will be held at the Grove Springs Hotel in that resort, on August 14th and 15th. The programme contains twenty-nine titles of papers to be read at the meeting. The secretary of the association is Dr. W. W. Smith, of Avoca, N. Y.

The Prince of Wales was elected an honorary fellow of the Royal College of Surgeons on the occasion of the centenary of the society's foundation on July 26th. His Royal Highness is now a full-fledged, all-around honorary medical man, the Royal College of Physicians having made him an honorary fellow some time ago. We believe he still lacks the honorary M.D., but he can buy that in Chicago for a pound or two.

The International Congress of Deontology and Professional Medicine was held in Paris on July 23d to 27th. Many subjects relating to medical ethics and to the dispensary and hospital abuse were discussed, but most of the papers were of local interest, dealing with conditions peculiar to France and happily unknown as yet in our own country. Some of the points of medical etiquette discussed were amusing in their triviality, and gave occasion to the exercise of an amount of casuistry that would have delighted a medieval theologian. Concerning the word "deontology," Dr. Grasset said it was created by Bentham, the British jurist, who published in 1747 a work entitled "Deontology, or the Science of Duty." Dr. Lereboullet, the president of the congress, defined medical deontology as the science of the duty of the medical man to the public, to his patients, and to his professional colleagues. Deontology sprang from the soul. It followed the principles of equity; it engendered a sense of refinement; it produced harmony; it obliterated strife; and, though the most vague, it was the most powerful force, directing the life and the daily acts of the physician.

Recognition of a Predecessor of Pasteur.—A monument has been erected at La Teste de Buch, in the Department of the Gironde, France, to Dr. Jean Hameau, the humble practitioner whose study of viruses, published in 1836, partly anticipated the discoveries of Pasteur.

Sir William MacCormac was unanimously re-elected president of the Royal College of Surgeons of England for the fifth time at its centenary meeting on July 26th. Sir William Savory was president for three years in succession, but Sir William MacCormac holds the record for length of service.

The Lunacy Exhibit at Paris.—Secretary T. E. McGarr, of the State commission in lunacy, has been awarded the first prize at the Paris Exposition for the best exhibit showing the progress made during the past hundred years in the care of the insane. Mr. McGarr's exhibit of photographs, statistics, and working models collected from all parts of the country form a complete presentation of the progress in the therapeutics of insanity in the United States during this century.

A Leper Colony in the Philippines.—A board consisting of Major Louis M. Maus, surgeon, Capt. George P. Ahren, Ninth Infantry, and Capt. W. E. Horton, assistant quartermaster, has been convened by General McArthur in Manila to select an island in the Philippine archipelago for the segregation of lepers, to prepare plans and estimates for suitable buildings thereon, and estimates of salaries for the necessary officials and employés. The board is also charged with fixing the ration and other allowances for the support of such leper colony.

The Medical Work in China.—The army medical staff of the Department of California has begun preparations for the care of sick and wounded in China, initiating its work by sending out twelve ambulances and fifty hospital tents. Some uneasiness has been caused by the breaking out of glanders among the twelve hundred horses at the Presidio stables belonging to the various cavalry regiments and awaiting shipment to China. As soon as the presence of glanders was discovered, the eight infected animals were shot, and it is hoped an epidemic may be averted.

Sewage in the Seine.—Despite the rapid succession of congresses on medicine and hygiene in Paris this summer, the health conditions of that city are far from satisfactory. The water-supply is so limited that it is shut off a large portion of each day, and it is feared that an actual water famine may be experienced. Then the sewer system seems to have broken down, and vast quantities of filth are poured into the Seine because the territories at a few miles' distance from Paris which were to receive it for agricultural purposes are not sufficiently extensive. The manufacturing dis-

tricts close to the capital have apparently no sewerage system at all, with the consequence that below Paris, all along that picturesque bend of the Seine which extends as far as St. Germain, the river is charged with filth of all sorts and sends forth horrible emanations.

Davos.—The health-resort companies at Davos-Platz and Davos-Dorf have combined, and the two resorts will be conducted under one management to be known as the "Kurverein Davos."

The Study of Tropical Medicine.—It is stated in *The Lancet* that the Liverpool School of Tropical Medicine has received a communication from the expedition which was despatched last month to America *en route* for Brazil, to the effect that, at the suggestion of Surgeon-General Sternberg, the expedition had joined for a short period the official yellow-fever expedition which the government has just despatched to Cuba.

The Plague in London and Hamburg.—Four cases of plague were discovered on a steamer arriving at London from the East the first of this month. The disease was among the Lascars in the crew, and two of those affected died. A case has also been discovered on a ship recently arrived at Hamburg from the Orient. In both cities all possible precautions have been taken to prevent the spread of the disease.

Dr. Frederick E. Potter, of Portsmouth, was unanimously nominated for governor of New Hampshire by the Democratic State convention on August 1st. Dr. Potter is a graduate of the medical department of the University of Vermont in 1860. As elections usually go in New Hampshire, there is not much danger that the candidate will be forced to give up his practice in order to discharge gubernatorial duties.

Gagging the Contract Surgeons.—An interesting fact has come to light in connection with the inquiry which the British government has instituted into the hospital management during the war. The civilian surgeons employed in the military hospitals have been required by the British Army Medical Department to sign a contract not to divulge in any way what their impressions may be on hospital matters.

The Cecil County (Md.) Medical Society.—At a meeting held August 2d, Dr. William T. Skinner, of Glasgow, Del., read a paper on "Typhoid Fever with Particular Reference to the Temperature Range." Dr. Howard Bratton, of Elkton, Md., presented a communication on "Some of the Unusual Manifestations of Typhoid Fever." Dr. A. Robin, of Newark, Del., read a paper on "The Widal Test, with Demonstrations."

The Lehigh Valley Medical Association.—The twentieth annual meeting of this association will be held at the Neversink Mountain Hotel, near Reading, on Thursday, August 16th. The programme includes: (1) The president's address, "Relation of Medical Professions to the Physical Culture of Children," by Dr. Israel Cleaver, of Reading, (2) the address upon invitation of the Berks County Society, by Dr. J. Milton Duff, of Pittsburg, on "Modern Obstetrics"; (3) the annual address before the Lehigh Valley Medical Association, by Dr. F. A. Harris, of Paterson, N. J., on "Certain Pathological Conditions of the Fallopian Tubes of Interest to the General Practitioner."

The Eyesight of School-Children.—Dr. Wallace Pyle, who was commissioned by the Jersey City board of education to examine the eyes of the pupils of Public School No. 1, has submitted a report of his investigation. He examined three hundred and fifteen pupils. Of these only sixty-nine had perfect eyes, and seventy-one of the whole number were in danger of permanent injury because of neglect to provide them with glasses. In the majority of cases the defect was slight and capable of correction by glasses. There were nine cases of trachoma.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending August 4, 1900. July 28th.—Medical Director G. W. Woods detached from the naval hospital, New York, August 18th, and ordered home and to wait orders. Medical Director H. J. Babin ordered to duty in charge of the naval hospital, New York, August 18th. Passed Assistant Surgeon L. L. von Wedekind detached from the *Indiana* and ordered to the naval hospital, Chelsea, Mass., for treatment. Assistant Surgeon M. K. Elmer ordered to the Boston navy yard, August 1st. July 31st.—Pharmacist F. T. Gordon warranted pharmacist from July 25, 1900. August 1st.—Passed Assistant Surgeon T. W. Richards detached from the *Machias* when put out of commission, and ordered to the *Indiana*. Assistant Surgeon C. H. Delancy ordered to additional duty at the naval hospital, Newport, R. I. Assistant Surgeon A. Stuart detached from the *Yankton* and ordered to temporary duty on the tug *Fortune* at the New York navy yard, August 4th.

Obituary Notes.—Dr. Elisha Chenery died at his home in Boston on August 1st. He was born in Livermore, Mass., on August 23, 1829. He began the study of medicine at Bowdoin College, and afterward entered Harvard Medical School, from which he was graduated in 1853. In 1862 he passed for a surgeon in the army, and started for the front, but soon after was taken ill, and compelled to resign. After thirteen years of practice in Maine, he went to Massachusetts, residing three years in Cambridge, and since 1870 in Boston. He was a member of the Maine Medical Association, also a fellow of the Massachusetts Medical Society, and a member of the American Medical Association.

Dr. Frederick W. Hulseberg was killed recently by a Filipino sniper near Majajay, fifty-five miles from Manila. He had been in charge of the hospital there for several months. He was born in India, but came to this country from England while a boy. He was in the insurance business in this city for several years, and then entered the Yale Medical School. Upon graduation he was appointed on the house staff of the Connecticut General Hospital in New Haven, but resigned to enter the army as acting assistant surgeon, and was sent immediately to the Philippines.

Progress of Medical Science.

Journal of the American Medical Ass'n, Aug. 4, 1900.

Four Cases of Malaria Associated with Acute Abdominal Pain.—J. A. Capps reports a number of cases from the Massachusetts General Hospital, in all of which (1) there were intermittent fever, nausea and vomiting, and enlargement of the spleen; (2) there was acute abdominal pain of such intensity that exploratory laparotomy was considered by men of experience; (3) the acute pain subsided along with the fever and with the other symptoms after the administration of quinine; (4) typical intracellular forms of the tertian parasite of malaria with motile pigment granules were present in the peripheral blood, but were never very numerous; (5) leucocytosis was invariably absent; (6) a considerable degree of anæmia of the secondary type existed. The pain was attributed to some coexisting disease or to neuralgia from malarial poison, or to both combined. Multiple neuritis in malarial subjects, supra-orbital and intercostal neuralgias, cardialgia, enteralgia, etc., are discussed with the pathology of the condition. Periodicity, enlargement of the spleen, and especially the finding of organisms in the blood, lead to the diagnosis in cases of abdominal pain of obscure origin.

Myomectomy per Vaginam.—J. Riddle Goffe points out the value of myomectomy as contrasted with hysterectomy for fibroids, and the superiority of the vaginal method, carrying out his conservatism in gynæcological surgery. He believes in removing the diseased portions but saving the uterus. Three illustrative cases are reported, in which the general rule is followed that uteri presenting small fibroid tumors are usually retroverted. He believes that the displacement affords the necessary conditions for the development of the tumors, and that the origin is very close to interference with the circulation as a cause. The facility afforded by the vaginal method of approach for the cure of the retroversion is an additional factor in its favor. There is also less danger, convalescence is smoother and simpler, there are no visible scar and no danger of hernia.

Myofibroma Uteri.—H. J. Boldt finds the greatest number of these tumors to be encapsulated and readily enucleated. He believes that fibromyomata arise from the muscularis of the capillaries. The greatest number of adenomyomata, however, have their origin in the Wolffian body. The various changes which may occur in fibromyoma are discussed. Sarcoma is to be suspected if a tumor long stationary begins to give rise to complex symptoms. Abdominal hysterectomy in the hands of an expert should not give a greater mortality than simple ovariotomy. There is a limited field for electricity, but only for palliative treatment, and it is indicated only in interstitial growths of moderate size. Ligation of the uterine arteries is a method which does not bear the test of time.

Arrhythmia Cordis Complicating Fibromata Uteri.—J. W. Bovée concludes as follows: (1) Arrhythmia cordis is not yet well understood; (2) as a complication of fibromata uteri it is exceedingly rare; (3) it has a serious import, the degree of which depends upon the condition causing it; (4) its presence as a complication of conditions requiring surgical operations necessitates a careful inquiry into its cause before the operation is performed; (5) it is a contraindication of more or less influence in all cases requiring surgical operation; (6) if not due to a severe pathological lesion other than that for which the operation is to be performed, its presence does not necessarily prohibit operation, but offers an additional obstacle to the patient's recovery.

Improved Technique in Major and Minor Surgery of the Female Generative Organs.—By H. R. Newman.

The Value of Section Work and how to Advance it.—By Edwin Rosenthal.

The Angiotribe in Abdominal Surgery.—By H. M. Taylor.

The New York Medical Journal, August 4, 1900.

Hysteria; its Nature and Etiology.—C. L. Mix believes that hysteria in its local manifestations is limited to psychical processes. Although the disturbed centre is in the cerebral cortex, still all the manifestations of hysteria appear in all possible territories of the nervous system. The nature of the disturbance of the cerebral cortex may be one of three types: (1) There may be a deadening of the sensory excitability of the cerebral cortex resulting in symptoms of hypæsthesia, anæsthesia, hypalgesia, and analgesia; or a deadening of the cortical motor discharge, resulting in paresis and paralysis. (2) There may be an intensification of the perception of the entering impulse manifested by hyperalgesia and hyperæsthesia; or an intensification of the energy of the motor discharge, resulting in spasms and convulsions, often reflex in character. (3) There may be confusional interpretation of entering impulses, manifested by symptoms of paræsthesia; or confusion in the motor discharge of cortical cells, resulting in hysterical ataxia, and in such contractures as are due to the imperfect distribution of motor impulses to groups of opposing muscles. Predisposing causes include heredity, age, sex, protracted and exhausting diseases, sexual disorders, and faulty home-training. Exciting causes are psychical and physical trauma, suggestion, and various toxæmias.

Appendicitis; When to Operate.—J. H. Carstens advises to operate when the diagnosis is made, except when the environment is bad, when no experienced operator or proper facilities are at hand, and in mild first attacks. As regards diagnosis, he says that if we bear in mind that in most cases the patient first complains of pain in the region of the stomach with more or less nausea, and has a high temperature, but notice that, as often happens in such cases, the pain in the region of the stomach and the nausea subside within twenty-four hours, and that the only soreness complained of is in the region of the appendix (always assuming that opium has not been given), then we shall not make a mistake very often in diagnosticating appendicitis.

On the Treatment of Metacarpal Fracture.—Carl Beck believes that metacarpal fragments can be invariably held in place by elastic pressure. For this purpose two rubber drainage tubes of moderate size are chosen, which are lightly pressed into the adjoining interosseous spaces so that they fill them up to a certain extent. They are kept *in situ* by adhesive-plaster strips. Thus the recurrence of the displacement is prevented. The whole is surrounded then by a moss splint, a material which, after being dipped in cold water, adapts itself to the contours of the hand like a plaster-of-Paris splint, over which it possesses the great advantages of being absorbent and much lighter.

Glandular Complications of Acute Follicular and Acute Suppurative Amygdalitis when Accompanied with Grippe.—W. C. Phillips has found this class of cases quite frequent during the past year. The disease has in some cases involved the superficial, in others the deep, glands. The cases generally present the usual type of grippe symptoms with follicular tonsillitis, the patient's apparent recovery being followed by pain in the side of the neck, a very extensive swelling, and a rise of temperature. Suppuration has occurred in his experience in about half the cases. In one instance, long streptococci were found in the pus.

A Case of Enlargement of the Liver and Spleen Succeeding Chronic Catarrhal Cholangeitis.—By S. S. Cornell.

The Present State of the Galvano-Caustic Operation of Bottini for Ischuria.—By Grenville MacGowan.

Vulvo-Vaginitis in Children.—By H. B. Sheffield.

Boston Medical and Surgical Journal, August 2, 1900.

The Transportation of Disease by Dust.—Harold C. Ernst says that of the irritant action of dust upon the respiratory apparatus there can be no doubt, as is illustrated by the photomicrographs of the dust from the streets, which show a variety of minute jagged particles of mineral and vegetable origin. This material also carries living forms of the higher bacteria. E. Germano has thoroughly studied the subject of the possibility of the transmission of pathogenic bacteria by dust. He concludes that it is a settled matter that they must be dry to render their transportation by dust at all probable. The bacteria of typhoid, cholera, plague, influenza, and gonorrhœa resist drying for so long a time that their chances of transmission are slight. The streptococci, pneumococci, and diphtheria bacillus may be carried by dust, as they show great variation in their resistance to drying. The diplococcus intracellularis, the staphylococcus of suppuration, and the bacillus of tuberculosis are still more resistant to drying, and the spore-producers—anthrax, malignant œdema, tetanus, etc.—may resist drying for an indefinite period. The conclusion would seem to be that the danger from dust is greater from its direct irritant qualities than from the chance of transportation of any infectious disease.

The Effects of Dust on the Upper Respiratory Tract.—Samuel W. Langmaid says that for many years he has observed that whenever a dust-storm occurred there was an outbreak of sore throats. Recovery from swelling and ulceration of the larynx in tuberculosis of the throat is made much more difficult by the irritating effects of a dusty atmosphere. The author scores the senseless way in which macadamized streets are cleaned; the constant watering, with almost no sweeping, together with the attrition of the surface by passing vehicles, soon pulverizes the surface and leaves a layer of dirt which is again wet down, to be later transformed into clouds of dust under the influence of strong winds. Better pavements should be put down in the beautiful and expensive city of Boston, where probably more irritating dust can be found in the atmosphere than in any other region east of the Mississippi River.

Effects of Dust upon the Lungs.—Vincent Y. Bowditch urges agitation in Boston in regard to obtaining an abatement of the "dust nuisance." He recalls good work already done by medical men in reference to street watering, but says that in consequence of the lack of proper pavements the citizens of Boston have had to endure in this open winter a vile atmospheric condition. He has patients with delicate throats and lungs who have to be housed absolutely, when with the streets in proper condition they could enjoy the mild, bracing air out-of-doors. Asphalt is not an ideal pavement, but with proper care and regulation to prevent its being constantly torn up or replaced by inferior material, it has thus far proved in our American cities the one which possesses the greatest advantages and the fewest disadvantages of all pavements used here.

Asphalt Pavements; their Nature and Desirability.—By Clifford Richardson, expert on asphalt, New York.

Recurrent Luxation of the Ulnar Nerve.—By F. J. Cotton.

Philadelphia Medical Journal, August 4, 1900.

Antistreptococcic Serum: a Case in Which it Was Used with Apparently Remarkable Results.—D. H. Galloway reports the case of a young woman suffering from a large swelling, believed to be an abscess, in the neck. The patient's condition was critical, but an operation was deemed inadvisable. Antistreptococcic serum was administered in a dose of 10 c.c., and repeated the following day and again two days later, as the supposed abscess was diminishing in size. Six doses in all were given. There was no positive proof that the swelling in the neck was a streptococcic abscess. If it was, however, the author thinks, there could be little doubt that the antistreptococcic serum saved the patient's life, for neither of the consultants believed she would survive either with or without an operation.

Congenital Tuberculosis.—Benjamin F. Lyle reports the case of a child born at term, of a mother who was practically moribund of tuberculosis at the time. The child was evidently ill from the time of its birth; its temperature was subnormal during the first four weeks, then for twelve days was slightly above normal, and finally hyperpyrexia ensued. The appetite was good until the second week before death, which occurred about ten weeks after birth. Post-mortem examination showed tuberculous deposits in the lungs, liver, spleen, kidneys, and bronchial glands. The author thinks the case was one of congenital tuberculosis.

A Case of Conjunctival Burn; Recovery Without Symblepharon.—By Howard F. Hansell.

Morbid Conditions Caused by the Bacillus Aerogenes Capsulatus.—By William H. Welch.

The Early Recognition of Ectopic Pregnancy.—By DeWitt G. Wilcox.

Medical News, August 4, 1900.

The Treatment of Summer Diarrhœa in Infants.—C. G. Kerley says the true nature of summer diarrhœa is not appreciated by the rank and file of the profession. If we can bear in mind that in so-called "summer diarrhœa" we have a disease due to virulent organisms, much will be accomplished. The child is poisoned. Cholera infantum is due to direct infection. There is a tendency for summer diarrhœa to get well if left to itself. The treatment is simple, consisting chiefly in elimination and diet. Irrigation is of value by means of a soft catheter, No. 14 English. The writer has discarded the white of egg in milk in favor of dextrinized barley. Opium must be used with great caution. The utmost cleanliness must be observed in preparing the infant's food.

The Consumptive in Los Angeles.—William H. Duckman says many patients with phthisis come annually to Los Angeles. Many arrive exhausted and gasping for breath, only to die within a few days. The family physician is too often responsible for permitting this. There is no approach to a specific remedy. Country life in the open air, easily digested food, precautions against negligence, and striving to get well are the essentials.

The Methods of Closure of Abdominal Incisions.—By M. H. Richardson.

The Lancet, July 28, 1900.

Carbohydrates and Disease.—E. Pritchard and E. H. Colbeck enumerate as the chief methods on which the organism relies for the disposal of supplies not requisite for ordinary physiological processes: (1) Complete metabolism by the tissues, with removal by the excretory organs (luxus consumption); (2) loss of appetite, vomiting, diarrhœa, and protective coating of the absorbing surfaces with excess of mucus; (3) the metabolism of the food into incompletely oxidized end products and their removal from the body with more or less detriment to the organism; (4) growth of normal tissues (hypertrophy), and growth of degenerate tissues (mucoid, amyloid, adepoid); new growths (tumors, granulations), and leucocytosis; (5) loss of tissues, discharges (purulent, mucous, serous, etc.), and hemorrhage; (6) active metabolism with the production of heat (fevers); (7) development of kinetic energy, restlessness, spasms (tonic and clonic); (8) parasites. They study especially certain clinical problems suggested by the third heading of the foregoing list. They believe that an excess of carbohydrates is responsible for many diseased conditions such as rachitis, rheumatism, and diabetes. This condition of carbohydrate excess they designate as glycosachthæmia. The article goes quite extensively into certain problems in physiological chemistry which cannot be followed here.

Tachycardia Following Enteric Fever.—C. Burland treated two hundred and sixty-five cases of enteric fever on one of the transports returning from South Africa to Southampton. The lowest pulse rate in this series was 72 per minute and the highest was 150, an average exactly of 95.25. In fifty-six per cent. the pulse rate was 80; in twenty-five per cent. it was 95; in ten per cent. it was 100; in five per cent. it was 110; and in four per cent. it was from 120 to 140. All the cases were in the convalescent stage when seen by the writer, whose attention was attracted by the uniformly rapid pulse rate. He thinks this may have been due to the great privations to which the patients had been subjected previous to their illness. The treatment was simple, consisting of free stimulation with brandy and champagne, while digitalis, carbonate of ammonia, and strychnine were the drugs chiefly relied upon, the latter being administered hypodermically in several extreme cases.

A Case of Abscess of the Parotid Gland Presenting Unusual Symptoms.—In a boy aged ten years, under the care of W. J. Beveridge, the helix of the ear was tilted forward by an abscess situated in the groove behind; the position of the zygoma was marked by a hard groove, below which there were œdema and deep fluctuation; and there was considerable œdema over the temporal region and extending down to the mastoid process. Both tonsils were slightly swollen. The pus sac behind the ear was opened, and in twenty-four hours an incision was made into the parotid and a gauze drain inserted. Considerable pus came away in the course of a few days, and the œdema gradually subsided.

A Further Note on the Influence of the Temperature of Liquid Hydrogen on Bacteria.—A. Macfayden and S. Rowland find that no appreciable effect is produced on the vitality of such organisms as bacilli acidi lactici, typhosus, diphtheriæ, anthracis, coli communis, and staphylococcus pyogenes aureus, etc., by immersing them in tube cultures in liquid hydrogen, in which for about ten hours they are exposed to a temperature of −252 C. The hydrogen was contained in a vacuum-jacketed vessel immersed in liquid air.

Addison's Disease and Leucoderma.—Samuel Wilks, who was a pupil of Addison, says that many cases of leucoderma have been sent to him during the last half-century as supposed cases of Addison's disease, but in no single case has this assumption proved to be true. The paper is in the main a historical study of the status in clinical medicine of Addison's disease, and a repudiation of certain views concerning its relation to leucoderma which the writer asserts have been wrongly attributed to him.

The British Medical Journal, July 28, 1900.

Oral Sepsis as a Cause of Disease.—William Hunter says that for every case of gastric or other affection traceable to pyorrhœa alveolaris a hundred are found associated with other dental and oral conditions of sepsis. All the various stomatitides are septic in nature and often connected with bone disease (teeth), and no pus organisms are so virulent as those grown in connection with bone necrosis. Mouth asepsis is to be secured by: (1) the direct application to the diseased tooth or inflamed gum of carbolic acid (1.20), repeated daily for just so long a period as the patient will persist in keeping his necrosed tooth or fang, still better (2) the removal of all diseased useless stumps, (3) the most scrupulous daily sterilizing by boiling of every tooth-

plate worn; and (4) on the part of dentists the avoidance of too much conservative dentistry and of the use of contrivances like "bridges" which cannot possibly be kept aseptic.

A Case Bearing upon the Pathology of Acromegaly.—P. G. Lodge relates a history in which there was stiffness of the right knee, which wore off gradually during the day, but soon became constant. There were swelling, prominent veins, and pain on motion. Nine months after amputation for round-celled sarcoma the hands began to enlarge, and enlargement of the other knee occurred. The patient died. It was thought that secondary deposits might have involved the pituitary body and thus caused enlargement of the hands. No autopsy was made.

Hysteria in the Male.—W. T. Greene relates the following case. During a paroxysm of pain from ingrowing toe-nail there was complaint of severe heart-pain, and the patient slid from the chair to the floor and was seized with violent paroxysms, throwing himself about, striking the head, and snapping with the teeth at friends who tried to restrain him. On recovery there was no recollection of what had occurred. The single attack was attributed to nervous exhaustion as a result of severe pain in the toe.

Dark Sclerotics and Fragilitas Ossium.—A. Eddowes has observed the tendency to broken bones in those having very dark sclerotics. At the recent meeting of the Dermatological Society of Great Britain he showed such a case and mentioned others. Surgeons seem not to have noted the association. The transparency of the sclerotics indicates a lack of fibrous tissue in the framework of various organs, and might explain the want of toughness in the bones of these individuals.

A Case of Aneurism of the Abdominal Aorta Pointing Posteriorly, in which the Initial Symptoms Were those of Chronic Colitis.—A. Ernest Maylard gives a case of a patient who showed a marked pulsating swelling in the back close to the spine, which was for a long time puzzling. The patient died suddenly by probable internal rupture of the aneurism.

Functional Diagnosis of Kidney Disease.—L. Casper and P. F. Richter advocate the use as a test of phloridzin followed by ureteral catheterization. They find that upon the introduction of this substance the body reacts through the separation of a sugar whose place of origin is in the kidneys. After the introduction subcutaneously of a quantity of phloridzin, it is found that healthy kidneys excrete within one-half an hour to one hour equal quantities of sugar. A damaged kidney will excrete less than its healthy neighbor. If the disease is far advanced the excretion of sugar is reduced to a minimum or is entirely absent. The authors believe that further experiments along this line will enable us to make the diagnosis of renal affections more accurately than has hitherto been possible.

Methods of Identification of the Tubercle Bacillus, with Demonstrations and Practical Employment.—Max Wolff enumerates three methods of identification, namely, the microscopical, cultivation in media, and inoculation of healthy organisms with a pure culture. The latter may be done subcutaneously, through the abdominal cavity, in the anterior chamber of the eye, and by inhalation. The various details of all these methods are fully set forth. Finally he says that inoculation may occur through the digestive tract, as can be experimentally proven, and also we can inject directly into the blood. The article contains nothing especially new, but is an excellent *résumé* of current methods of experimentation.

A Hitherto Unrecognized Property of Alcohol in the Sterilization of the Hands.—Braatz comments on the two views that have been taken regarding the rôle played by the alcohol which is so prominent a factor in most of the methods of hand-disinfection. It is maintained by some that it is mainly through its property of dissolving fat that it is useful, for in this way the corrosive-sublimate solution is enabled to come into closer contact with the skin, while other observers claim for it great intrinsic antiseptic power. It is a fact, however, that other substances, such as ether, which are better solvents of fat than alcohol, or bodies which surpass it in germicidal power, alike fail to produce the same good results, and we are furthermore between the horns of the dilemma, since the more nearly absolute the alcohol is, the greater is its fat-dissolving faculty, while the more water it contains, within limits, the better it acts as an antiseptic. The author endeavors to clear up the matter by advancing the theory that it is in abstracting air from the pores and fissures of the skin that the true value of the application lies; a previous treatment with alcohol enables subsequent aqueous solutions to penetrate much more thoroughly and completely into all the macroscopic and microscopic interstices of the cutaneous surface.

The Early Diagnosis of Tabes.—Erb emphasizes the necessity for watchfulness to avoid overlooking incipient or atyphical forms of this malady. In evidence of the protean character of the disease he cites five case histories in which there were practically no objective symptoms at all, and even subjectively the disturbances present were of the slightest, consisting variously of obscure lancinating pains, slight hyp- or hyper-æsthesia, lassitude, diminished sexual vigor, headache, etc.; pupillary sluggishness or inaction was, however, noted in several instances. On the other hand, a case is reported in which the patient was not suffering from any subjective symptoms whatever, and yet on examination was found to have lost his tendon reflexes and to give both Romberg's and Westphal's symptoms. In doubtful cases the author considers the presence or absence of a syphilitic history as of the greatest importance; when preceded by a specific infection symptoms which otherwise would be negligible assume the gravest significance. It is in the recognition of these anomalous types of the disease (the formes frustes of French observers) exhibiting a tendency to run a sluggish course or even apparently lie dormant for years, that the greatest care is needed, for these are precisely the cases which seem most amenable to treatment.

Alcohol Dressings.—Graeser has found permanent applications of strong (ninety-per-cent.) alcohol of great service in combating all inflammatory conditions in which there is a tendency toward suppuration. The explanation offered is that the alcohol by the chemical irritation produced causes a local dilatation of the blood-vessels, and the richer blood-supply means an increased formation of alexins and consequent greater capacity for resisting the spread of infection. The technique employed consists in the application of thick layers of gauze which are saturated with alcohol and then covered with some impervious material, such as gutta-percha paper. The dressing is left in place for days at a time, but about once every twelve hours it is necessary to resaturate it with alcohol.

The Preparation of a Bubonic-Plague Serum from the Peritoneal Exudate of Infected Animals.—Terni and Bandi emphasize the disadvantages and dangers connected with the preparation and use of the serum made according to Haffkine's method. It is necessary to have very virulent cultures of the bacteria. It is difficult to obtain the serum in any quantity and the immunity produced does not manifest itself until ten or twelve days have elapsed, while if the individual inoculated has already been infected the treatment would only serve to aggravate the severity of his disease. With the idea of producing a serum that might be obtained in large quantities in a short space of time, and in which there should be present substances capable of conferring on the organism a passive immunity, making it able to resist infection until the moment when active immunity should have been caused, they experimented with the peritoneal exudate of rabbits into whose abdominal cavities virulent cultures of plague bacilli had been injected. This serum contains pure cultures in abundance, and after fractional sterilization and the addition of small quantities of carbolic acid, sodium carbonate, and sodium chloride, it is ready for use. No disadvantages at-

tend its employment; it may be readily obtained in considerable quantities; the determination of the dose for each individual lot of serum is easily and quickly effected; experiments on man and animals show that no local or general disturbances are produced, and immunity appears earlier and is of longer duration than is the case with the serum of Haffkine.

The Theory of the Pasteur Inoculations for Rabies.—Marx formulates his belief as follows. The virus of rabies is modified, but not killed, by its passage through rabbits. On subsequent injection into man, in consequence of its diminished activity it is killed before it can reach the central nervous system. The constituents of the disorganized microbes are thus set free, and by their presence the necessary stimulus is given to those organs which produce the specific anti-bodies for rabies. Experiments on monkeys showed that while they promptly succumbed to injections of the virus of street rabies, they were resistant to virus that had been passed through the bodies of rabbits. When the infection, instead of being made subcutaneously or intramuscularly, was effected by injection into the chambers of the eye the monkeys died with characteristic symptoms.

Nectrianine.—Mongour and Gentes describe experiments carried out with nectria ditissima in cancer. The drug nectrianine is derived from the parasitic fungus of the so-called cancer of trees. The external aspect of these vegetable cancers is often strikingly similar to the appearances of cancer in the human being. Cultures of the fungus show cylindrical conidiæ, an illustration of a pure culture being shown. The following conclusions are drawn from the first communication of Bra and Mongour and from the present observations: (1) Injections of nectrianine are without danger. (2) In none of the patients affected with cancer did the treatment arrest the evolution. (3) It did not prevent the production of tumors at a distance, nor modify the glandular enlargements. (4) The normal course was pursued. (5) In most cases hemorrhage was decreased and there was less fetid discharge. Most of the cases had already reached an advanced stage. Further tests are justifiable in spite of the unfavorable showing.—*Le Bulletin Médical*, July 18, 1900.

Salt in the Alimentation of Epileptics.—Edw. Toulouse gives a résumé of his observations and experiments which go to show that by diminishing the amount of salt in the food of epileptics the therapeutic action of the bromides is in a large measure increased. The previous work of Ch. Richet and himself in this direction is referred to. Tables give the results of tests, showing the effects of increased and diminished salt supply in reference to the result obtained from bromide medication. The author thinks the fact established that decrease in salt supply intensifies the effect of the bromides, and that the bromide of sodium seems to be the least toxic and to approach more closely in nature the sodium chloride which it should replace.—*Gazette des Hôpitaux*, July 21, 1900.

Pneumonia in the Obese.—H. Huchard believes that in the prognosis of pneumonia we cannot regard the degree of virulence of the microbe by itself. Among other elements to be reckoned with is that of obesity. In treatment of pneumonia in fatty subjects we can employ: (1) bleeding, either local or general; (2) digitalis, not with the aim of introducing a cardiac tonic and not with the end in view of meeting a morbid intoxication with a remedial intoxication; (3) milk diet and diuretics (theobromine); (4) chloride of sodium.—*Journal des Praticiens*, July 21, 1900.

A New Sign of Alcoholism.—Maridort describes a sign which he learned from the late Professor Quinquaud. It consists in a series of quick tappings or the sensation of slight shocks made by the phalanges when the patient's fingers are spread apart and extended and pressed perpendicularly against the palm of the experimenter. It is only after a few seconds that the phalangeal shock is felt, and then only in case the subject is an alcoholic.—*La Médecine Moderne*, July 18, 1900.

American Journal of the Medical Sciences. August, 1900.

Clinical Notes of Cases of Pernicious Anæmia.—F. P. Henry finds in well-marked cases of this disease (1) a reduction of the number of the red corpuscles to a degree that is normal in the cold-blooded animals. It is the rule to find in this disease, when well advanced, less than 1,000,000 corpuscles per cubic millimetre. Figures like these are normal in the cold-blooded animals. (2) In pernicious anæmia many of the corpuscles are much increased in size, so much so that they have received the name of megalocytes. Many of them are quite as large as the corpuscles of the lizard and eel. (3) They often show a tendency to assume an oval outline, which is that of the corpuscles of the cold-blooded animals. (4) Finally, to make the resemblance complete, nucleated red corpuscles are commonly present in the blood of pernicious anæmia. The clinical facts brought out in the paper are evident from the following case-headings. Case I.—Profound anæmia, with all the characteristics of the pernicious type; peripheral neuritis, with paralysis of extensors; bronzing of skin, with freckle-like spots upon its surface. Result fatal. Case II.—Profound anæmia following repeated epistaxis; characters of the blood as regards number of red corpuscles and percentage of Hb. the same as those of pernicious anæmia; convulsions following transfusion, the giver of the blood being epileptic; continued fever; death. Case III.—Extreme anæmia, with percentage of color higher than that of number; marked gastro-intestinal disorder; great improvement under the use of arsenic and orexine. Case IV.—Under observation six years, during which there have been several slight and two severe relapses, chronic gastro-intestinal catarrh, with marked exacerbations preceding and during the relapses; complete restoration to health. Case V.—Extreme anæmia of less than one year's duration; pleuritic effusion of left side; death from erysipelas.

Pernicious Anæmia; a Study of One Hundred and Ten Cases.—R. C. Cabot gives the results of his examination of these cases, including blood counts. From this analysis he makes up a composite symptomatology as follows: (1) a slow, insidious onset without recognizable cause; (2) remarkable freedom from pain; (3) striking absence of emaciation (in most cases); (4) the frequent presence of symptoms suggesting disease of the spinal cord; (5) paroxysmal attacks of diarrhœa and vomiting, occurring without any obvious relation to diet or to treatment, preceded and followed by periods in which digestion and absorption were performed without apparent difficulty; (6) the tendency to great spontaneous improvement in all the symptoms, followed by rapid and inevitable relapse; (7) a reduction in the red corpuscles to a point below 2,000,000 per cubic millimetre, without a corresponding reduction in the hæmoglobin; a reduction in the number of leucocytes, and especially in the number of polymorphonuclear neutrophiles; the presence of large numbers of oversized, well-stained red corpuscles, some of them containing nuclei (megaloblasts), together with a tendency to abnormal staining reactions and to an oval shape in the red corpuscles.

The distinctive features in the diagnosis of secondary or symptomatic anæmia are: (1) the presence of a well-recognized cause; (2) the steady progress of the symptoms, especially in malignant disease. If gastro-intestinal symptoms are present they seldom improve spontaneously; (3) emaciation; (4) the blood.

Minor Form of Cardiac Dilatation.—Beverley Robinson finds this condition in anæmic girls just past the age of puberty. They suffer from menorrhagia, constipation, and flatulence. The cardiac fluttering so often seen in these cases, and generally considered functional, he believes to be due to actual organic change requiring iron and oxygen, rest and massage, and restricted hours of mental effort. But they also require, and in the beginning of treatment it is absolutely essential, small repeated doses of strychnine and digitalis until their hearts sufficiently respond to enable us to make satisfactory use of other means to restore bodily activity. In these cases the action is as a rule rapid, and the first sound is exaggerated and seemingly irritable. Our best results come from the strychnine and digitalis in moderate doses for a week or two, to be followed by a prolonged course of iron.

Experimental Research Showing that Uric-Acid Secretion is Not Regularly Diminished in the Periods Preceding Epileptic Seizures.—J. J. Putnam and F. Pfaff examined the twenty-four hours' urine from two patients, the test being made twenty-nine times. The tabulated results cannot be said to bear out the statements which have been so emphatically made, either as regards the low excretion before the epileptic attacks or the high excretion after them.

OUR LONDON LETTER.

(From our Special Correspondent.)

SOUTH AFRICAN HOSPITAL COMMISSION—SPECIAL EXTRAORDINARY MEETING OF THE BRITISH MEDICAL ASSOCIATION; ATTEMPT OF THE COUNCIL TO DISFRANCHISE MEMBERS AND CAPTURE THE FUNDS AND MANAGEMENT OF THE ASSOCIATION—LEAD AS AN ABORTIFACIENT—FINSEN'S TREATMENT BY LIGHT—COMMISSIONS AND GUARDIANS—NATIONAL HOSPITAL FOR PARALYSIS.

London, July 20, 1900.

On Tuesday Mr. Balfour was able to give the names of the additional members he had agreed to place on the commission of inquiry into the army hospitals in South Africa. The gentlemen chosen are Sir David Richmond, ex-lord provost of Glasgow, and Mr. Frederick Harrison, general manager of the London and Northwestern Railway Company—our largest railway. Both men have experience of the sort likely to prove useful, Sir David in administrative affairs, and Mr. Harrison's knowledge must be most important in considering transport. But Mr. Burdett-Coutts was not satisfied, and gave another demonstration of his want of that common-sense recommended by Lord Roberts. Mr. Coutts endeavored to controvert the ruling of the speaker and renew his attack on Professor Cunningham, but he was put into his place by the Speaker, to the delight of a chuckling House. Only one other person indorsed the silly notion that an examiner of army surgeons in anatomy must be a tool of the War Office.

On Wednesday the extraordinary general meeting of the British Medical Association, called to pass the new regulations framed by the Council, was held in Exeter Hall, and most emphatically refused to sanction the alterations and by implication condemned the Council and all its works. The hostile tone of the meeting was evident from the first. The chairman, Dr. Ward Cousins, was scarcely equal to the occasion, genial and popular though he be. At times the meeting might be described as uproarious. The proceedings began by objection being taken to the presence of the solicitor to the Council, who was not a member of the association, Mr. Victor Horsley and Dr. Brierly pointing out that actions for libel (*sic*) might arise. On a vote he was directed to withdraw. Mr. Brown demanded that the opinion of counsel (Mr. Beaufort Palmer), under which the council of the association were acting, be read. This was done. Complaint was made that amendments of which due notice had been given had not been put upon the agenda paper. To this the secretary replied that counsel had advised that the wording of the notice of meeting precluded any amendment being moved (a smart move that on behalf of the Council!) After a suggestion of adjournment in order that the notice might be amended had been negatived, the chairman introduced the resolution. He much regretted that the solicitor had been excluded. He and Mr. Fowke were the best friends the association had. Amid much laughter and cries of "No!" he proceeded to draw a pathetic picture of these two officials toiling for the common good, while the members who laughed were comfortably asleep rolled up in their blankets. He said that the new articles were only aimed at the removal of discrepancies and contradictions, and that there was very little real difference between the existing and proposed new articles. The powers of the annual meeting would remain unaltered by the new articles. From this the chairman seems to have been completely hoodwinked.

Dr. Robert Thompson described the origin of the new articles. He pointed out the absurdity of the association's being ruled by an annual meeting at which often only thirty members were present.

Dr. Bernard O'Connor said the new articles would take away all power from the members and make the council absolute. This was done by what he would not call chicanery, but verbal subtlety.

Dr. Rentoul advocated that limited proxy-voting should be allowed at general meetings; no person to be proxy for more than fifty members, and such proxy voting to be allowed only on motions of amendment.

He also proposed that the representation of branches should be equalized and the Council reduced from one hundred and one to forty-seven members.

Dr. Douglas complained that members had for years maintained that the Council acted illegally in ignoring resolutions passed in annual meeting, and now this was admitted to be the case. The Council meant well, but did badly.

Mr. Victor Horsley, who was received with loud applause, said he himself had been ruled out of order under an interpretation of the articles that was now admitted to be illegal, but no apology was forthcoming. He urged the rejection of the resolution and the reorganization of the association after careful study of its needs, by a special committee if necessary.

Dr. Ritchie also opposed the resolution. He said that in drawing up these regulations the Council had ignored the recommendations of a committee appointed to consider the subject. The unattached members were not considered.

On the resolution being put, it was declared that the three-fourths majority necessary to pass it was not obtained. Apparently an absolute majority of those present voted against it.

From the foregoing you will see that the little plot laid by the Council to capture the absolute control of the association and the disposal of its funds has been frustrated. For once the members have seen through the scheme and taken the trouble to refuse assent to changes in the articles of association which might open the door to years of litigation or throw away all the rights of present and future members. A more barefaced attempt could scarcely be imagined. A special meeting called at Exeter Hall to consider some amendments of the articles worded in such a way as to require close attention to grasp their effect—then if that passed without comment the confirmation could be secured next week at Ipswich by one of the old dodges by which the Council has too often secured the passing of its proposals. It is desirable that the general meetings at Ipswich should be fully attended, lest some fresh pettifogging move be attempted.

Professor Wright, of Netley, has been permitted by the director-general to publish the official statistics concerning the anti-typhoid inoculations of the Ladysmith garrison. There were 1,705 inoculated; of these 35 had typhoid, 1 in 487, and the deaths numbered 8, or 1 in 213. The non-inoculated numbered 10,529; of these, 1,489 contracted typhoid, or 1 in 7.07, the deaths being 329, or 1 in 32. These figures at first sight seem to speak well, but have to be discounted by various considerations. Taking the proportion of deaths to the total number of attacks in the two groups, we find it to be 1 in 4.52 in the non-inoculated and 1 in 4.4 in the inoculated. The case mortality, therefore, was not influenced much, if at all, by inoculation, but this point is of less import than the reduction in incidence. It is hardly possible to determine at present the protective power of inoculation, and there seems a probability that different preparations have been used. But on the whole Professor Wright regards the results as encouraging in animals, inasmuch as they show that the proportion, on the one hand, of attacks and, on the other hand, of deaths from typhoid fever was seven times smaller in the inoculated than in the uninoculated. It may, too, be borne in mind that the figures would have been more favorable if those who had previously suffered from typhoid could have been subtracted from the number of uninoculated.

Those who are less hopeful than Dr. Wright cannot say that so far statistics are discouraging, and the enormous importance of typhoid seems abundantly to justify any reasonable experiment. The fact that anti-typhoid inoculation has, I believe, never been followed by serious results should induce any one exposed to its dangers to submit to the procedure.

Cases have been published in the journals during the last few years in which lead-poisoning has occurred from diachylon or some other preparation being taken with the intention of producing abortion. Dr. Ransom, of Nottingham, has added three cases in which cerebral symptoms were prominent, and says his experience leads him to believe that the use of diachylon as an abortifacient is a fast-growing evil. Further, he has obtained from others statements of their experience which quite corroborate this conclusion, and he thinks diachylon should be classed with poisons.

Finsen's "light treatment" is being tried rather fully at the London Hospital, where a department has been fitted up for the purpose with all necessary appliances.

The local government board has warned other guardians that the irregularities at St. Pancras as to commissions may have occurred in their districts, and stating that relieving officers who had been guilty of such practices should not be allowed to continue in office.

The board of the National Hospital for the Paralyzed and Epileptic has replied to the complaints of the staff in a most feeble defence. It declares that the question arises because the staff do not approve of the board allowing patients who can afford to pay to participate in the charity of the hospital. "Supposing that were true," when a board asserts a right to sell the services of the honorary staff to those who can afford to pay, it is high time for the staff to say No.

Malaria.—Methylene blue may be given with confidence whenever quinine is indicated.—Smithwick.

Society Reports.

THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

Held in Paris, August 2, 3, 4, 5, 6, 7, 8, and 9, 1900.

(Special Cable Report to the MEDICAL RECORD.)

GENERAL SESSIONS.

First Day—Thursday, August 2d.

THE first general session of the Thirteenth International Medical Congress was largely attended, nearly all of the six thousand members of the Congress and their ladies being present. The opening session was held in the enormous Salle des Fêtes at the end of the Champ de Mars in the Exposition grounds. This great hall, which had been constructed from the old Machinery Hall of the Exposition of 1889, is said to have a seating capacity, when all its space is utilized, of about fifteen thousand. Its expanse of roof, covering an area of about one hundred thousand square feet, is unbroken by a single column, and were its acoustic properties perfect it would be unrivalled among the assembly buildings of the world. The hall, large as it is, was completely filled, and the gala dresses of the ladies and the glittering uniforms of the many dignitaries and military surgeons present made a brilliant scene. The hour appointed for the opening of the Congress was two o'clock, but it was long after this time when the loud rapping of the president's gavel hushed the roar of conversation which was filling the auditorium.

Addresses of Welcome.—M. Loubet, the President of the French Republic, who was to have opened the Congress, was unable to do so, and the pleasant task was delegated to the Minister of Justice. He dwelt upon the satisfaction which Paris and all France felt when, at Moscow three years ago, the representatives of the medical profession throughout the civilized world united in accepting the invitation of the French delegates to hold the thirteenth triennial session in Paris, during the continuance of the Exposition which marked the close of the most progressive century the world has ever seen. Officially as an officer of the Government of France and as the appointed delegate of the President of the Republic, and personally as a humble citizen of Paris and of France, he extended a hearty welcome to the members of the Congress and to the ladies who accompanied them. He was sure their deliberations would result in the advancement of the sublime healing-art, and he confidently hoped that their stay would be a pleasant one—if it was not it would not be the fault of their hosts—and that they would always look back upon the Paris Congress as one of the greatest of the illustrious series of medical reunions.

Address of the President.—M. LANNELONGUE, president of the Congress, then delivered his address, taking as his theme the importance and the value of international congresses, particularly of those called to discuss medical subjects. They tended to promote international intercourse, to break down national prejudices, and to cement the bonds of a common humanity. Whatever the nationality of the individual, each and all belonged to the one great profession of medicine, and this great fact was exemplified and emphasized in no better way than by these international assemblages of medical practitioners.

After this, the presidents of the national committees of the various countries were presented to the congressists and spoke briefly in acknowledgment of their introduction. All were received with applause, but among them Lord Lister was conspicuous by reason of the volume and duration of the acclamation accorded him. Von Bergmann, of Berlin, representing Germany, made a few most enthusiastically received remarks in glorification of France, which he said was the cradle of surgery and of pathological anatomy. He recalled the names of some of the great surgeons of France and of the pioneers in that country in the study of pathology, whose labors had established the foundation upon which the great medical structure was now being erected. Kitasato, of Japan, was among the speakers.

Traumatism and Infection.—PROF. RUDOLF VIRCHOW delivered the first of the general addresses, taking as his subject the relation of bacterial infection and traumatism. A trauma, he said, became harmful to the organism when it opened a portal for the admission of pathogenic micro-organisms, and when it so weakened the individual cells of the tissues that they were unable to overcome the microbes. All was not over when the specific bacteria had invaded the organism, for then began the struggle between them and the vital cells of the body, a struggle which was called disease. If the intruders were too strong, either absolutely by reason of their invincible virulence or of their overwhelming numbers, or relatively because of the weakened resisting-power of the cells, the latter were more or less speedily overpowered, the organism succumbed in the unequal contest, and disease resulted in death. If, on the other hand, the micro-organisms were present in attenuated form or in small numbers, and the cells were in the enjoyment of their normal vital activity and had not been paralyzed by the shock of the initial injury, then the invading bacteria were vanquished and infectious disease was at an end. The province of medicine was to aid these cells in repelling the assaults of the invading hordes by whatever would strengthen the cells or weaken the microbes.

This address was regarded by Virchow's hearers as a full recognition by the great pathologist of the part played by bacteria in the pathogenesis of disease.

At the conclusion of Virchow's address, which was marked by great applause, the president announced that, owing to the lateness of the hour, Professor Pavloff's address, which was on the programme for this day, would be postponed to the second general session to be held on Monday.

The opening session of the Congress was then adjourned.

The President's Reception.—On Friday evening M. LANNELONGUE gave a reception to the members of the Congress and their ladies. The occasion was a brilliant one. It was marked by an excellent concert and the usual buffet supper. Many men of international reputation were present, among them Potain, Pozzi, Dieulafoy, Virchow, von Bergmann, Waldeyer, Weigert, Ehrlich, Ewald, Boas, Kitasato, Sforza, Yersin, Surgeon-General Van Reypen, U.S.N., Weir, Keene, Jacobi, Janeway, Maragliano, Babes, Baginsky, Marfan, and others.

Second Day—Monday, August 6th.

The second general session was held on Monday, the fifth day of the congress, in the grand amphitheatre of the Sorbonne, the proceedings being opened soon after 2 P.M. by M. Lannelongue, the president of the congress. It was announced that the total number of registration of members of the congress was 6,170. Of this number no less than 412 were Americans, the United States being fourth as regards attendance in the list of nations, France of course being first.

Experimental Therapy as an Aid to Physiological Research.—PROFESSOR PAVLOFF, the delivery of whose address was postponed from Thursday, was unfortunately unable to be present on account of a

sudden indisposition, and his oration was therefore read by Dr. Likhatcheff. The address was entitled "Experimental Therapy as a New and Extremely Fecund Method of Physiological Research." The author presented numerous illustrations of the solution of physiological problems, mainly effected through the light thrown upon the subject by the results of therapeutic measures. Physiologists were for a long time greatly embarrassed in their attempts to explain why death occurred after section of the vagus nerve in animals. This was due partly to the complex distribution and function of the nerve. Three solutions were offered: (1) It was assumed that dissolution occurred from suffocation in consequence of paralysis of the laryngeal muscles supplied by the recurrent branch of the pneumogastric nerve; (2) others believed that apnœa resulted from hyperæmia and œdema of the lungs following upon the disturbances of pulmonary circulation and of respiratory function caused by loss of cardiac and pulmonary control; (3) others again attributed the fatal result to distention of the stomach and decomposition of its contents. These suppositions were based upon the well-known results of division of the nerve. There was a loss of sensation and of power in the larynx, cardiac action was at first accelerated and then impeded, the respiratory movements of the chest wall were retarded, the *besoin de respirer* was dulled, and the pulmonary capillaries became distended, the mucous membrane was congested, and inflammatory appearances were noted in the lung tissue; finally the secretory activity of the peptic glands was checked, the cardiac orifice of the stomach was paralyzed, food stagnated and decomposed in the viscus, and the organ became distended. Now, however, all these supposed inevitable changes could be prevented by appropriate treatment, and animals in which the tenth nerve had been divided no longer of necessity died. The death of the organism, this association of individual organs, was found not to be necessitated by the abolition of function of any organ, except, of course, a vital one such as the heart. We were able to treat successfully each organ as an individual, and upon early recognition of the disturbed function we might correct it or supplement it by a vicarious action in some other organ; indeed the machinery of the organism often adapted itself to the new requirements without our aid. As an example of experiment therapy, the results of which had contributed greatly to advance the science of physiology, the speaker referred to the treatment of myxœdema and of cretinism by means of preparations of the thyroid gland.

Some Pathological Problems of the Present Day.—Prof. Burdon Sanderson, of Oxford, then delivered an address with this title. He passed in review the history of the cellular theory of morbid action, citing the experiments and teachings of Schwann, Robin, Kolliker, Cohnheim, and Virchow down to the beginning of the bacteriological epoch in 1878. Pathologists were formerly interested chiefly in the study of inflammatory processes, since this study seemed best adapted to bring out into clearer view the cellular theory and to elucidate some of its unsolved problems. Now, however, the attention of all was concentrated upon the study of micro-organisms as the active agents in the excitation of morbid processes. This devotion to micro-biology had resulted in good in other directions. For example, it had contributed not a little to progress in histology, having led among others to the discoveries of Golgi and Cajal concerning the minute anatomy of the nerve structures—discoveries which might revolutionize neural pathology and therapeutics. It had also led to a plausible explanation of cell-function—that is to say, of the differences in function exhibited by cells of similar appearance and of the chemical action of cells upon each other—this explanation being that the action of the cell was dependent upon the presence of a special ferment developed within the cell itself as a result of its metabolic activity. The author's theory of inflammation was that it was a morbid process resulting from injury to the tissues caused by chemical noxa, but that these were not necessarily of bacterial production. He believed in the existence of two types of morbid action—toxic and biotic. In the first the poison was the exciting cause of the pathological process, in the second this was the result of the vital action of the infecting micro-organism.

American Medicine.—Prof. A. Jacobi, of New York, then delivered an address entitled "La Médecine et les Médecins dans les Etats-Unis" (see p. 201). The distinguished speaker was greeted warmly by the audience, in which were many citizens of his adopted country. Upon the conclusion of this oration the second general session was adjourned. The third and closing general session of the congress will be held on Thursday afternoon.

Reception by the Ladies' Committee.—On Monday evening a reception was given by the French committee of ladies to the members of the congress and their families in the Palace of the Luxembourg. The reception was a brilliant one, but the crowd was too great for comfort.

Third Day—Thursday, August 9th.

The closing session of the congress was held in the amphitheatre of the Sorbonne under the presidency of M. Lannelongue. The attendance was not so large as it had been at the two previous general sessions, and those present were attracted chiefly by the desire to learn the name of the recipient of the Moscow prize.

The Architecture of the Bones of Man and Animals was the title of an address delivered by Professor Albert. The speaker showed how nature, in shaping the skeleton so as best to bear the weight it was obliged to support in the different vertebrates, had followed the same rules as those man had evolved through long experience in the construction of his buildings. In other words, the rules of architecture were those of nature.

Award of the Moscow Prize.—At the opening session of the Twelfth International Medical Congress in Moscow in 1897, Prince Gallitzin, the mayor of Moscow, in his address of welcome announced the foundation by that city of a prize to be awarded at each succeeding congress to the person who in the period elapsed since the preceding meeting had done that medical work deemed to have been of the greatest benefit to humanity. The value of the prize was 5,000 francs ($1,000), and it had been established by the city as the most fitting expression of its appreciation of the honor bestowed upon it in its selection as the place of assembly of the Twelfth International Medical Congress. The first prize was awarded at the Moscow congress, on the motion of Professor Virchow, to M. Henri Dunant, the founder of the Red Cross Society, who was then living in straitened circumstances in Geneva. The second award was made, M. Lannelongue announced, to Señor Ramón y Cajal, of Madrid, for his great work in the study of the nervous elements, the possible benefits of which to mankind were incalculable.

The Fourteenth Congress, the president then said, would be held in Madrid in 1903, the medical faculty of the University of Madrid being charged with the arrangements for the meeting. This announcement was greeted with loud and prolonged applause, at the subsidence of which Professor Fernandez, the representative of Spain, rose and thanked the members of

the congress in his own name, and that of his country and the city of Madrid, for the honor which had been done them in the selection of the capital of Spain as the meeting-place of the next congress.

The president then announced the closure of the Thirteenth Congress in a brief speech, expressing his appreciation and that of his colleagues of the honor the congressists had done them in responding in such numbers to the invitation extended to them three years ago.

THE WORK OF THE SECTIONS.

On Friday the session of the Section on Medicine (Pathologie Interne) was devoted entirely to a discussion of diseases of the stomach and intestine.

Gastric Ulcer.—Dieulafoy read a paper on this subject. The size of such ulcers, he said, might vary from a mere point to a solution of continuity of the area of a silver dollar. After a brief review of the symptoms and complications common to all forms of gastric ulcers, he referred at some length to certain special types. The smallest of these was the so-called erosion which occurred in the form of bleeding points. Those might be numerous and, despite their small size, might give rise to an abundant hæmatemesis. Sometimes one or more solutions of continuity of greater size were formed in the gastric mucous membrane, to which the author gave the name of exulceratio simplex. Although usually superficial, these erosions might extend to the arterioles lying beneath the muscularis mucosæ and result in violent and even fatal hæmatemesis. The simple ulcer was the type of chronic gastric ulcers with a tendency to perforation. Finally there were the specific syphilitic or tuberculous ulcerations, which might also lead to hemorrhage or perforation. It was not rare to see cancer engraft itself on an ulcer of the stomach.

The subject was further discussed by Ewald and Bourget, the latter dwelling especially upon the surgical aspect of gastric ulcer and emphasizing the importance of operation in cases of threatening or actual perforation. Cohnheim read a paper in which he described his new oil treatment of gastralgia, Einhorn presented a communication on idiopathic dilatation of the œsophagus, and Hemmeter one on intestinal peristalsis.

Muco-membranous Enteritis was discussed at some length. Mannaberg, of Vienna, said that a distinction should be made between membranous enteritis and mucous colic, the former being a subacute or chronic catarrhal affection of the large intestine accompanied by evacuations especially rich in mucus, the latter being a morbid condition characterized by paroxysmal crises of colic followed by the evacuation of masses of mucus. The former was simply a catarrh of the large intestine, the latter was a neurosis associated usually with hysteria or neurasthenia. Some of the exciting causes of mucous colic were affections of the genital organs (male or female), psychical disturbances, constipation, and organic intestinal disorders. It was often accompanied by achylia gastrica, nervous dyspepsia, or enteroptosis. The pathological anatomy of membranous enteritis was the same as that of enteritis in general, but in mucous colic there were no appreciable lesions of the intestine.

Boas, of Berlin, said that muco-membranous colitis was a peculiar catarrhal affection marked by a tendency to the formation of mucous casts of the colon. Alongside of this, the more common form, there was another in which, in the interval of the paroxysms, there was no special trouble except constipation; this latter affection was called mucous colic. The symptoms of muco-membranous colitis were constipation, colic, spasmodic atony of the intestine, the presence of mucous or membranous masses in the stools, and a general neurotic state. The clinical course of muco-membranous colitis was absolutely parallel with that of habitual constipation, and measures which would cure the one would cure also the other.

Mathieu, of Paris, discussed this subject chiefly from a therapeutic standpoint. Constipation, he said, was at once the cause and the effect, and presented the chief indication for treatment. In combating it, it was necessary to employ measures which would not increase the secretions, the pain, or the tendency to spasm; castor oil, large enemata, and belladonna were the best remedies. The former might be given in small doses with the morning coffee. The injections should be made slowly with but little pressure, the fluid being at a temperature of about 40° C., and from a pint and a half to two pints and a half in amount. Simple boiled water, solutions of borax or salicylate of sodium, or a weak solution of the neutral ichthyolate of ammonium might be used. Belladonna was often given with good results. Warm local applications and warm baths often exercised a beneficial effect. The general neurotic condition should be treated with nerve sedatives and hydrotherapy. The patients being often weak and emaciated, tonics and a generous diet were indicated.

Pulmonary Œdema.—On Saturday in the same section the question of œdema of the lungs was discussed. Von Basch, of Vienna, said that œdema was due to an arrest of the capillary circulation in the pulmonary alveoli, resulting from the increased blood pressure in the left auricle, and to the afflux of blood from the right heart. The mechanical consequences of these two conditions were a dilatation of the alveoli and an increased resistance of the alveolar walls. In addition there was a transudation into the alveoli in consequence of the stasis in the pulmonary circulation. Dependent upon these morbid conditions occurred a mechanical obstruction to respiration and imperfect aeration of the blood, whence arose dyspnœa. Exudation alone without dilatation and intra-alveolar tension would not cause dyspnœa in any such degree as was generally supposed; indeed, the dyspnœa and cardiac asthma might be developed in the prodromal stage of pulmonary œdema prior to the occurrence of alveolar exudation.

Masius, of Liége, held that pulmonary œdema was of the same nature and pathogenesis as œdema in general, its special characteristics being the result primarily of its location. He recognized three forms —inflammatory, static, and toxic—the second of which was by far the most frequent.

Teissier said that there was clinically a special morbid syndrome to which the term acute œdema, or serous apoplexy of the lung, might justly be applied. This condition should be carefully distinguished from other forms of pulmonary œdema of slow evolution and mechanical origin. It was characterized by a premonitory tickling in the throat or a painful intrathoracic tension, by violent dyspnœa, accompanied by a cough and often by a pinkish, frothy expectoration, and by a multitude of fine râles all over the œdematous region. For the occurrence of acute pulmonary œdema a previous infection (rheumatism, influenza, typhoid fever, pneumonia), or intoxication (Bright's disease, less frequently alcoholism) was necessary. Another essential to its production was some lesion of the heart at its base, in the region of the coronary arteries or in the left ventricle, the exciting cause being something (a cold, strong emotion, excessive fatigue) which produced cardiac spasm or failure. Under this influence, a rapid elevation of pressure in the pulmonary vessels being produced, the already existing blood changes favoring serous exudation, and

the concomitant vasomotor troubles favoring stasis, acute œdema of the lungs would readily occur. Those three pathogenic conditions were typically existent in cases of interstitial nephritis, in which pulmonary œdema was of frequent occurrence. The therapeutic measures which the speaker favored were bloodletting, revulsives, atropine, amyl nitrite, and in some cases rectal injections of carbonic acid gas.

Treatment of Pneumonia.—Vaillard discussed the treatment of infectious pneumonia, the main indication in which was the expulsion from the system of the metabolic products of the pathogenic bacteria. This could best be accomplished by blood-washing—copious venesection combined with intravenous injections of a decinormal saline solution, or artificial serum. The elimination of the toxins and the increase in the resisting-powers of the body were also favored by the cold pack and other forms of hydrotherapy.

Gastro-Enteric Infections in Infancy.—This was the subject of discussion in the Section on the Medical Diseases of Children.

Escherich, of Graz, read a paper on "The Rôle of Micro-Organisms in the Gastro-Intestinal Diseases of Nursing Infants." After referring to a number of examinations made by him and his assistants determining the presence of microbes in the stools of infants, he said that the introduction of any micro-organisms other than those normally present in the intestine, whether the new-comers were pathogenic or not, might cause fermentation of the intestinal contents.

Baginsky, of Berlin, divided these affections into functional (acute dyspepsia) and organic. Of the latter he distinguished the following: (1) Lesions of a catarrhal nature: (*a*) subacute dyspeptic catarrh, (*b*) superacute catarrh, cholera infantum, (*c*) chronic gastro-intestinal catarrh, and (*d*) intestinal atrophy, intestinal cachexia, or athrepsia. (2) Lesions localized in the follicles: (*a*) simple follicular enteritis, (*b*) grave infectious follicular enteritis, dysentery. The functional troubles as well as those accompanied by anatomical alterations were caused by: (1) Endogenous infections or intoxications: (*a*) the direct action of the normal intestinal microbes, the virulence of which is exalted by certain conditions of high temperature, etc.; (*b*) the action of the toxic products elaborated from the alimentary substances under the influence of these virulent microbes. (2) Ectogenous infection or intoxications: (*a*) the action of saprophytic microbes or those common infections introduced with the food and becoming virulent by the favoring circumstances of high temperature, etc.; (*b*) toxic substances already present in the ingested food.

Fede, of Naples, read a paper dealing chiefly with the symptoms and treatment of the chronic forms of gastro-enteritis in infancy. A brief consideration of the anatomical and physiological imperfections of the digestive apparatus of the new-born, he said, would suffice to prevent surprise at the frequency of catarrhal gastro-enteritis, particularly the chronic forms in infancy. The chief symptoms were an obstinate diarrhœa, rectal prolapse, vomiting, fermentation of the gastric contents, and dilatation of the stomach. Among the general symptoms we see pyrexia due to auto-toxæmia of intestinal origin, debility, cachexia, marasmus, and various respiratory, glandular, nervous, renal, and cutaneous complications. Among the sequelæ were Parrot's athrepsia, rickets, Riga's disease, and tuberculosis. The primary indications in the management of chronic gastro-enteritis of infants were for the institution of hygienic measures and an appropriate diet—that is to say, breast-milk. Elimination and disinfection of the intestinal contents were very important, and among the remedies most suitable for these purposes were castor oil, calomel, benzonaphthol, and lavage of the stomach and intestine with solutions of boric acid, carbolic acid, creolin, etc. For the diarrhœa, when too profuse, lactic or hydrochloric acid, preparation of bismuth, tannin, or other astringents were indicated. In cases of pain and nervous excitement, poultices, calmatives (belladonna or even opium), and baths were indicated. When depression was marked, aromatic baths, quinine, caffeine, ether, asafœtida, musk, and injections of artificial serum might be employed.

Marfan, of Paris, followed with a communication on the etiology and pathogenesis of these affections. He divided them, according to their exciting causes, into (1) dyspeptic gastro-enteritis resulting from a faulty elaboration of the food, whether from over-feeding or from too early weaning; (2) primary infectious gastro-enteritis following the introduction of pathogenic microbes into the digestive tract by way of the mouth; (3) primary toxic gastro-enteritis resulting from the introduction into the digestive canal of some chemical poison; and (4) secondary gastro-enteritis which might follow any of a number of diseases. The action of the causes enumerated might, the speaker added, be intensified by extraneous influences, such as summer heat, catching cold, dentition, etc.

The subject was further discussed by Vargas, of Barcelona, and Epstein, of Prague.

Artificial Feeding.—Jacobi, of New York, read a paper on this subject. Human milk, he said, being of variable composition, it was impossible to manufacture an exact equivalent, and the demand for it had no justification. Water was a necessary addition to the infant's artificial food. A decoction of cereals was the proper diluent for the casein of cow's milk. Enough milk-sugar was contained naturally in cow's milk, and the added sugar should be cane—for one reason, because there was a ferment in the intestinal tract of the infant which rendered cane sugar assimilable. There was no necessity for adding fat to cow's milk. Finally common salt must be added to the infant's artificial food. Sterilized cow's milk was not a curative remedy nor an equivalent of human milk, but it was indispensable in cities and wherever pure, fresh milk could not be obtained.

Radiography in the Study of Fractures and Dislocations was the subject of a discussion in the Surgical Section. E. von Bergmann, of Berlin, referred to certain of the causes of non-union after fracture, such as the interposition of muscular fibres between the ends of the fractured bone. Unfortunately we could not diagnose this condition positively by means of the Roentgen rays, but we might be justified in assuming its presence when the image on the fluorescent screen showed the ends of the bone separated by a more or less wide interval, which was always of the same width in whatever position the limb was examined. Certain other causes of non-union, however, could be accurately revealed by the *x*-rays. In fracture of the patella, for example, we might discover by this means three obstacles: (1) Inequality in size of the two fragments, (2) multiple fracture, (3) rotary displacement of one of the fragments. In three cases radioscopy rendered incalculable service by revealing the danger of non-union and thus enabling the surgeon to institute appropriate operative measures. The speaker, thus forewarned, had obtained bony union in more than twenty-five cases of this nature. Another service which radioscopy had rendered was in revealing various fractures of the metatarsal and tarsal bones which were not recognized formerly, being regarded as simple sprains of the foot, and mistreated by massage.

G. Manoury, of Chartres, said that in cases of simple fracture radioscopy was of invaluable service in showing us the number of fragments, their form,

position, extent of overriding, and the location of detached splinters. In order to obtain a sufficient knowledge of the disposition of a fracture, we must radiograph it at two different angles—usually in front and in profile, but no precise rules could be formulated in this respect, for each fracture called for its own angle of observation. The clinical diagnosis of a fracture had lost none of its value since the introduction of radioscopy, but the latter served to fortify or sometimes to correct the former. Although this method of examination was useful in all cases of fracture, there were certain ones in which it was especially important, such as those of the upper end of the humerus, the lower end of the radius, the leg (especially those involving the tibio-tarsal articulation), the astragalus, and the metatarsal bones. Radiography was no less useful in the treatment than in the diagnosis of fractures, for it enabled us better to reduce the fracture and to determine how far this reduction was possible, to rectify any malposition before the callus became so firm as to necessitate refracture, and finally to determine the degree of perfection of the result of our treatment. It furnished us also with a means of estimating the relative value of the different forms of apparatus employed. In cases of complicated fracture, the necessary operative measures could be instituted much more intelligently, and we could determine in advance, in cases of impaction, whether and in what direction it would be necessary to saw the fragments in order to obtain freedom and apposition. The Roentgen rays were of much less value to us in the diagnosis and treatment of dislocations, yet even here they often rendered most valuable service. Unfortunately, however, radioscopy often failed to reveal the obstacles to the reduction of a luxation, since these were commonly in the soft parts. In the study of congenital dislocation of the hip and of the luxations occurring in the course of malum coxæ, on the other hand, the *x*-rays had been exceedingly serviceable.

Among other subjects of interest discussed in the various sections on Saturday were: "Tuberculosis in the Italian Army," by Sforza; "Tuberculosis in the French Army" by Arnaud; "Men of War in Time of War," by Surgeon-General Van Reypen, U.S.N.; the "Bacteriology, Symptomatology, Prophylaxis, and Orrhotherapy of Plague," by Simond, Yersin, and others; "Infection and Immunity," by Féré, Babes, Chantemesse, Maragliano, Nocard, Bernheim, and Ehrlich; "Toxins and Antitoxins," by Roux, Ehrlich, Pane, Vaillard, Vincent, and others; "Etiology of Yellow Fever," by Geddings of the United States Marine-Hospital service; "General Infections in Gonorrhœa," by Taylor, Lassar, and Tommasoli; "Notes on Recent Methods in the Surgery of Fractures, with Special Reference to Massage and Mobilization," by Pickett; "Treatment of Puerperal Eclampsia by Lavage of the Blood (Repeated Venesections and Injections of Artificial Serum)," by Seytre.

Gout.—In the Section on Medicine there was an interesting discussion on the pathogeny of gout.

Sir Dyce Duckworth, of London, said that an inherent vice of nutrition was at the bottom of gout, this vice being expressed by faulty metabolism in various organs such as the liver and kidneys. This trophic vice resulted in the formation of uric acid in excess and its occasional retention in the blood. The nutritional fault might be acquired or inherited, and when acquired might be transmitted to the descendants. The gouty paroxysms were marked by the precipitation of crystals of sodium biurate in the joints and other parts of the body. The influence which controlled these paroxysms, determining their location and their metastases, was nervous, probably bulbar. Articulations or tissues which had been weakened by injury or overuse were those which were most prone to be the seat of the gouty deposits, but the neurosis was the essential feature in the pathogenesis of gout. The presence of uric acid in the blood was in itself alone unable to produce a paroxysm of gout. The deposit of urates was usually permanent, but it might sometimes, especially when in the more vascular tissues, be removed by appropriate treatment. That the pain of gout was not caused by the uratic deposit alone was shown by the fact that enormous deposits might occur in gouty individuals without exciting any pain whatever. Gout was to be regarded as both a blood and a nerve disease, both hæmic and trophoneurotic changes being shown to act as pathogenic factors.

Prof. Wilhelm Ebstein, of Göttingen, held that gout was a more or less chronic malady, the fundamental substratum of which was an hereditary, usually congenital morbid tendency to which had been given the name of the uric-acid diathesis. One could only theorize as to the true cause of this diathesis. The close relations existing between the nucleins and uric acid made it probable that one had to do with an abnormal condition of the cellular nuclei or protoplasm. The individual predisposition, whatever this might be, which could often be traced through generations, was of the greatest importance in the uric-acid diathesis. Certain conditions might arise which were capable of converting this diathesis into actual gout. Among these might be mentioned the following: (1) Other things being equal, gout developed the earlier and the more surely, the more pronounced was the uric-acid diathesis; (2) luxury, idleness, and the abuse of alcohol favored the development of gout; (3) certain intoxications, acute or chronic, often excited an attack of gout in the presence of the uric-acid diathesis; among these might be mentioned bacterial poisons, lead, and the toxic principles of rheumatism, influenza, and syphilis; (4) contagion, which Boerhaave regards of such importance, was a negligible factor; (5) and finally climate appeared also to have no influence in the production of gout. Uric acid was the gouty poison *par excellence*, but whether other products belonging to the alloxur or nuclein bases were also concerned in the production of the disease, it was as yet unable to determine. The offending uric acid was probably that formed from the nucleinic substances of the organism and not that formed from the nucleins of the food. An excess of uric-acid formation seemed not, in itself, to be responsible for the gouty attack, for an enormous formation of this body was often noted in leukæmia without gouty symptoms. The inflammatory and necrotic changes in the tissues were the result of the presence of uric acid, and when the tissues were completely necrosed—but not before—there occurred a deposit of sodium-biurate crystals. Gout might be divided clinically into primarily articular and primarily renal; the first form was the more common and was not incompatible with long life, the second was a more serious malady due to retention of uric acid in consequence of an organic lesion of the kidney.

M. P. Le Gendre, of Paris, reviewed the various theories held at the present day regarding the pathogenesis of gout, and said that against each of them might be raised certain chemical, physiological, or pathological objections. Statistics proved that gout was associated very often with the so-called arthritic diseases, those due to a vice of nutrition, in the individual or his family; the most common of these associated maladies were diabetes and obesity. Diabetes consisted in an inability of the tissues to consume the sugar, to carry to its final equation the transformation of the carbohydrates, and it was most probable that there was in the gouty an inability to elaborate completely the nitrogenous principles.

Among the consequences of this incomplete destruction of albumin was a loading of the system with certain acids, which diminished the solubility of the uric acid present (not necessarily in excess) in the blood, and with certain organic bodies the toxic action of which might cause some of the symptoms of gout. Clinically there was seen also a morbid affinity between gout and interstitial nephritis. In cases of acquired gout the nutritive vice of the cells was brought about by a defective hygiene (abuse of nitrogenous food and alcohol, insufficient exercise and mental overwork) or by a poison such as lead.

Autotoxæmia.—On Wednesday there was an animated discussion on autointoxication, participated in by Bouchard, Ewald, Albu, Gautier, and Brouardel. The majority of the speakers accepted provisionally the theories of Bouchard regarding the pathogenesis of this condition. Two interesting papers on "Extrabuccal Alimentation" were read by Leube and Ewald (the latter will appear in the next issue of the MEDICAL RECORD). Chantemesse discussed the influence for good or ill of an exclusive meat diet upon the course of pulmonary tuberculosis. Blum described a new method applicable to the recognition and treatment of systemic intoxications. Menetrier presented a communication in which he traced the relation of adenomata to ulcer and carcinoma of the stomach.

Arloing read a paper dealing with the history of the attempts at orrhotherapy in combating tuberculosis, and describing the various researches, from Koch's to Maragliano's, made with the aim of producing a really efficacious and safe anti-tuberculous serum.

Among the communications presented by Americans in the various sections were the following: "Non-tabetic Lesions of the Spinal Cord," by Dana; "Treatment of Hypertrophied Prostate," by Ramon Guitéras; "Ischæmia and Atrophy of Muscles due to Tight Bandaging," by Bernays; "Surgery of the Lungs," by J. B. Murphy; "Report of a Case of Ligation of the Abdominal Aorta," in which the patient survived the operation forty-eight hours, by Keen; "Study of Tuberculosis in the United States," by de Schweinitz, of Washington; "A New Operation for Acute Appendicitis," by Weir.

Therapeutic Hints.

Rachitis.—

℞ Phosphori ..... gr. ss.
Ol. amygdal. dulc. ..... ʒi.
Pulv. acaciæ,
Pulv. sacch. alb. ..... āā ʒss.
Aquæ destil. ..... ʒiss.
M. S. Shake and give one to three tablespoonfuls daily.

—KASSOWITZ.

Painful Menses.—

℞ Codein ..... gr. i.
Chloral,
Ammon. brom ..... āā gr. xv.
Aq. camphoræ ..... ʒi.
M. S. From a quarter to half the quantity before retiring. Repeat as indicated.

Creosote Wine.—

℞ Creosote ..... ʒss.
Tinct. gentian ..... ʒi.
Spir. vini rect. ..... ʒviij.
Vini xerici ..... q.s. ad Oij.
In tuberculosis a dessertspoonful several times a day unless much fever is present.

—*Nouveaux Remèdes.*

Lupus Erythematosus.—Strong alcohol containing a little menthol. The patient carries about a vial and applies a few drops every half-hour or so.—HALL.

Dysentery in Childhood.—

℞ Cocain muriat. ..... .05 cgm.
Ergotin. ..... .50 "
Ext. opii ..... .10 "
Aristol ..... .25 "

Pulv. Doveri ..... gr. ss.
Sulphur. sublim.,
Sacch. alb. ..... āā gr. viij.
M. S. At dose. Repeat from two to ten times a day, p.r.n.

Ringworm of the Scalp.—Cut the hair short with scissors, and

℞ Chrysophanic acid ..... gr. xv.
Chloroform ..... ʒss.

Tie a piece of absorbent cotton on the end of a probe and apply to the dry scalp (do not wash the part), saturating the ringworm. One application will often cure. The ringworm will peel off in scales about the third day, and the second application is certain to complete the cure.—BASCOM LYNN.

Heat-Stroke and Sun-Stroke.—Local and general refrigerants. Friction and other measures aiming at restoration of consciousness. To control the thermogenic centres give antipyrin in drachm doses preferably by hypodermic injection.—MOUSSOIR.

Infant Feeding.—After the first two days the infant should be fed at regular intervals of two hours, and from one to one and a half ounces at each feeding. About the third month the intervals should be lengthened to two and one-half hours, feeding three and one-half ounces each time. The intervals should be constantly lengthened, until at the ninth to the twelfth month feeding should be three and one-half hours apart, and seven to nine and one-half ounces in quantity. Until the sixth week two feedings during the night should be allowed; one from the sixth week to the sixth month, when all night-feeding should be discontinued.—ROWELL.

Clinical Department.

REPORT OF A CASE OF CÆSAREAN SECTION.

By DAVID ST. JOHN, M.D.,

VISITING PHYSICIAN AND SURGEON TO HACKENSACK HOSPITAL, HACKENSACK, N. J.

Mrs. H. O——, aged twenty-five years, American, entered Hackensack Hospital on September 18, 1899, in the ninth month of gestation, and feared labor owing to marked spinal curvature existing from infancy. Her general health was good; she was undersized, of dark complexion, weight one hundred pounds.

The following measurements were determined by Dr. St. John and confirmed by Doctors White and Conover:

External between crests of ilium, 9½ inches; external between anterior superior spines, 10 inches; external between trochanters, 11 inches; external conjugate, 6 inches; diameter of outlet, only 2 inches.

Since it was evident that the fœtus could not be born "per vias naturales," Cæsarean section was advised.

The patient was placed upon nutritive diet; the bowels were regulated, daily baths were given, and the abdomen was thoroughly asepticized. Urinary analysis showed alkaline reaction, specific gravity 1.014, no albumin.

At intervals for several days the patient complained of some pains in the back and suprapubic region.

On September 25th, at 2:30 P.M., labor pains beginning, the patient was taken to the operating-room, catheterized, and the abdomen was again thoroughly cleansed with green soap, bichloride solution, alcohol, and ether freely. The operation was performed by Dr. St. John, assisted by Doctors Neer, Conover, Conrad, Swayze, and Scott, with the hospital nurses. A hot vaginal douche having been given, the cervix was dilated, and the vagina was loosely filled with iodoform gauze. Abdominal incision was then made in the median line, six inches long; there was no hemorrhage. The wall was thin, and the intestines were not in the way. The uterus was lifted out and surrounded by warm, sterile gauze. A longitudinal incision was made in the uterus five and one-half inches long; the amnion was punctured, and the opening enlarged with scissors. The child was grasped by the foot, lifted out, and handed to Dr. Conover to be cared for. The cord was clamped and cut. Uterine contractions immediately set in. The placenta having been loosened and delivered, the uterus was then cleared of remaining membranous shreds and loosely packed with strips of iodoform gauze, a strip for drainage having first been run through the cervix.

Dr. Conrad controlled uterine hemorrhage by compressing the uterine arteries with his hands. Thirty minims of aseptic ergotal was given hypodermically as soon as the uterus was emptied.

The uterine incision was then closed by two sets of sutures, the deep with No. 4 silk two-fifths of an inch apart, the superficial with No. 2 silk. The gauze was removed from the uterus before the sutures were tied. The uterus was cleaned of blood and returned to the abdomen. The pelvic cavity was mopped out, though this was little needed, for it had been well protected by sterile gauze and towels. The abdominal incision was closed with extra heavy silk. No drainage was used. The time under ether, which was given by Dr. Neer, was twenty-nine minutes; the time from the beginning of the first incision in the abdomen until the last suture was tied, twenty-four minutes. There was very little hemorrhage. She bore the anæsthetic well. The dressings used were iodoform, iodoform gauze, sterile cotton, and binder. Sterile salt solution was used during the operation.

The cervical drainage was removed on the 27th. The lochia were normal. Seven days after the operation the dressing was changed. The wound was clean and dry. The stitches were removed on the 21st day; the incision had perfectly united.

Twenty-five days after operation the patient sat up for a few minutes. After the first few days, during which time the patient was restless, requiring very careful nursing and stimulation, she regained strength rapidly, and was discharged from the hospital on November 6th, six weeks after the operation.

Mother and child are both well now. The child weighed seven pounds at birth.

Some authorities advise dilating the cervix after the uterus is emptied, but why should any time be lost during this important step in the operation, when it can be done so readily and with no need of haste, just before the abdomen is opened?

Although it is advised to bring the uterus out of the abdomen before incising in all cases in which sepsis is suspected, it would seem to be better to do so in other cases as well, owing to greater ease of handling. Uterine hemorrhage can be effectually controlled by an assistant grasping the uterus firmly low down near the neck with both hands, thus avoiding the dangers of subsequent atony or post-partum hemorrhage so apt to follow when a rubber ligature is thrown around the uterus.

FARADIC ELECTRICITY IN RENAL COLIC.

By CARL D. S. FRÜH, M.D.,

PHILADELPHIA, PA.

Henry H——, aged forty-eight years, was taken severely ill on June 22, 1900, with pains in the left kidney. He gave a history of three previous attacks in which the pains were so bad that he went into convulsions. The regulation treatment with morphine and atropine failed here even to give more than momentary relief. He was then placed on his side with the sore kidney up, the hip and legs elevated, and a faradic current interrupted sixty to eighty times per minute was applied to the front and back of the organ. One half-hour of this gentle tapping of the kidney eased the pain completely. The patient passed water freely and was completely relieved by this treatment.

July 2, 1900.

A LARGE OVARIAN CYST.

By W. C. FISHER M.D.,

CLARINDA, IOWA.

In January, 1900, in my capacity of county physician I was called to see Mrs. T——, eighteen years old, married almost two years. Her family history was good. Her mother and grandmother were still living. About eighteen months previously she had noticed pains in the region of the left ovary. Menstruation was irregular and painful. She noticed a tumor in that region, but did not think seriously of it. This continued with varied treatment until the summer of 1899, when a diagnosis of ovarian cyst was made and operation was advised. At this period she fell in with the faith healers and was sent to Chicago, where she received "spiritual treatment" for some time, but the tumor continued to grow. She returned from Chicago and continued the "absent treatment" plan until June 16, 1900, when I was asked to operate. I called to see the patient and found her suffering from shortness of breath, caused by the abdominal distention.

The cervix uteri was partially prolapsed through the vulva.

The woman was taking but little nourishment, because anything more caused vomiting. Her weight was about one hundred and sixty pounds. The measurement around the waist was fifty-five inches, her previous measurement having been twenty-one inches. She had been in the habit of sitting with the lower end of the tumor resting on a woven-wire cot.

I informed the friends that there was very little to hope from an operation, but it was the only hope, and if it was their wish I would operate. On June 20th, at their request, assisted by Drs. Torrens, Cokenower, and English, of this city, I operated. Upon opening the peritoneum I came upon a fibrinous mass filling the entire pelvic cavity, which had to be divided before I could bring it through the opening, which was about nine inches in length. After removing this portion I came upon a large cyst entirely filling the upper part of the abdomen and adherent to the peritoneum and diaphragm. This was filled with a dark-brown, syrupy fluid. After tying the pedicle and removing the sack, I flushed the abdomen with sterilized water, sutured with silkworm gut, and dressed in the usual manner. The patient recovered promptly from the shock, and her mental condition was clear. She did well, with no fever and a normal pulse (72) until Friday morning the 22d, when she suddenly collapsed and died in a few minutes. Upon opening the abdomen after death I found everything in nice shape; the stump was in good condition, there had been no bleeding, and the abdominal wound was healing rapidly. The tumor weighed seventy-five pounds.

ALCOHOL AS AN ANTIDOTE TO CARBOLIC ACID.

By GEORGE W. SARGENT, M.D.,

SENECA CASTLE, N. Y.

A good deal has been written of late in regard to carbolic acid, notably a paper by Dr. Seneca D. Powell, in the Medical Record of March 11, 1899. Powell says that carbolic acid may be applied to the skin in full strength without harm; that one may dip his hands in ninety-five-per-cent. carbolic acid with impunity if he rinses them promptly in ninety-five-per-cent alcohol.

A short time ago I involuntarily verified these statements to my own perfect satisfaction and that of several witnesses. I had on a table with other things two two-ounce bottles, labelled and filled, respectively, with carbolic acid and alcohol. Having washed my hands I purposed to rinse them in alcohol, and picking up one of the bottles rubbed a liberal amount of the contents over my hands as in the act of washing. I was not a little amazed to find by the oily sensation and silvery color of the skin that I had washed in the carbolic acid. I at once drenched well with alcohol from the other bottle, and was well pleased to see the normal color and feeling return.

Some cases have been reported in which diluted alcohol—and one recently in which pure alcohol—was poured into the stomach in carbolic-acid poisoning, with successful results.

I have learned that stronger ammonia acts similarly to alcohol as a local application, but it would hardly answer for internal use or for use on ulcerating surfaces or in suppurating cavities. Dr. Powell has proven that in such cases as the latter alcohol makes it possible to use carbolic acid in full strength with very beneficial results.

Carbolic acid and alcohol being so common, and so powerful for good or evil, it behooves every one to be familiar with their properties, and anything emphasizing the fact ought to be mentioned. This is the reason I have reported my little experience.

RECURRENT TRANCE.

By C. I. PAGE, M.D.,

LITCHFIELD, CONN.

The following case, which has been under my observation for a number of years, is such a peculiar one in many ways, that I believe a report will be of interest. Mrs. C. E——, aged ninety-one years, widow, mother of three children. There is no insanity in the family. In October, 1875, she was thrown from a wagon, striking her head on the edge of a plank. On examination a small scalp wound was found directly under the occipital protuberance. There were no indications of fracture. She was taken home in a semi-conscious condition, and she remained so for several days, with symptoms of concussion of the brain. At the end of two weeks she was able to perform her usual household duties and appeared to have fully recovered. About two months afterward, while reading, she remarked to her daughter: "I have a headache and feel sleepy, so will retire for the night." The next morning she was found in a deep sleep. On being shaken she awoke for a few seconds and answered questions, but directly was asleep again. She presented the appearance of being under the influence of morphine or an anæsthetic. She would not ask for food or water, but if either were placed to her lips she would eat and drink, but if not continually urged would stop. She did not evacuate the bowels or bladder unless kept awake and requested to do so. The superficial reflexes were diminished, eyelids closed, pupils dilated. There was no muscular rigidity. This trance continued for five days. She then awoke, and for a few hours there was a mild delirium. After this she seemed perfectly rational, but could not remember people she had seen, or conversation which had taken place during the trance. She did not mention her condition, but if it was mentioned she would discuss it freely. She then remained awake continually for four days, and would sit all night reading, sewing, or in conversation with her attendant. At the end of this time she would again sleep. In this manner she lived for twenty-five years, asleep five days, then awake four. This condition of wakefulness and sleep would come with such clock-like regularity that her attendants could tell almost to the hour when she would awake or sleep. As to this condition being genuine there cannot be the least doubt. The woman's mental powers while she was awake were much better than those of the average person at seventy-five years of age. In April last she developed bronchitis and while in a trance died. An autopsy was refused.

A DEATH FROM THE SCHLEICH MIXTURE.

By R. M. STONE, M.D.,

OMAHA, NEB.

It becomes my painful duty to report a death in my practice from the use of the Schleich solution. As yet I have not seen one recorded in the American experience with the solution. As anæsthetist of the Presbyterian Hospital, it fell to me to give the solution to a young woman aged twenty-three, well nourished and fairly robust in appearance; the heart sounds were not clear and sharp, but there was no valvular lesion. She took it kindly and had corneal anæsthesia in six minutes and surgical anæsthesia in two more; she was

carried to the operating-room, and the last preparation was complete in about three minutes more. She was to be operated upon for chronic appendicitis, having recently recovered from her second attack.

After these eleven minutes, the pupils were very small, the lower jaw was relaxed, and anæsthesia was apparently profound as it usually is in my experience with the Schleich solution. The surgeon asked if she was ready, to which I said she was. He made the incision, to which there was a very small reflex; when he separated the muscles, there was a little more. During all this time, I had continued the dropping of the solution at an increased rate because of the flinching. The surgeon had removed the appendix, when the following sequence of events took place. (It should first be said that the incision and separation of the muscles had not caused sufficient reflex to dilate the pupils; they were still small, and the pulse and color were good.)

The pulse then became weak, irregular, intermittent, and then ceased; the respiration, which had been regular, became very rapid for six or eight respirations; while the pulse was failing, but before it had ceased the pupils were observed to be small; instantly they dilated widely, and death was present. Efforts at resuscitation were continued for an hour, with no response whatever. Death had taken place from paralysis of the heart centre, followed by that of the respiratory.

No more horrible experience can happen to a physician than this. It is a dreadful shock to him, and causes him to review his work most carefully and to criticise himself harder than any of his enemies will dare to. Having done this, I can say that my four hundred and forty-one administrations of the Schleich solution, with serious symptoms in only thirteen, and death in but one, still allow me to think that its administration gives more quiet, more freedom from nausea and vomiting during and after, and greater safety, than either ether or chloroform.

A CASE OF DOUBLE FACIAL PARALYSIS.

By GEORGE J. PRESTON, M.D.,

PROFESSOR OF NEUROLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE.

Paralysis of both facial nerves, occurring simultaneously, is sufficiently rare to warrant the recording of the following case: The patient, a widow aged sixty-five years, had always enjoyed excellent health. She was very well nourished, and her organs were all normal. A few days prior to my visit she had an attack of what her family physician pronounced bronchitis, accompanied by cough, slight fever, and general neuralgic pains. It is important to note that there was at this time a mild epidemic of grippe prevailing. The patient's symptoms were not such, however, as to warrant a diagnosis of influenza. I saw her on June 25th and found that she had a marked facial paralysis of the peripheral type, involving both upper and lower branches of the left nerve; the face was strongly drawn to the right, the tongue was protruded to the left, the left eye could not be closed, etc. There was no impairment of sensation either general or special. On the 27th, or two days later, I saw the patient again and found that the right nerve had become involved. The face, which had been strongly drawn to the right, was now perfectly straight, but practically motionless and without expression, a veritable mask. The patient was unable to close either eye, and there was a very distressing flow of tears. Speech was much affected, and the movements of the tongue were limited. There was no disturbance of taste, smell, or hearing, and general sensation was entirely normal. A careful examination showed no trace of the involvement of any other nerves, cranial or spinal.

The paralysis gradually improved under strychnine in increasing doses and the galvanic current. In a couple of months the left side was practically well and the right was much improved. I saw this patient a year and a half after the attack, and her general health was excellent. She said that the right side of her face was not yet natural, but there was hardly any paralysis remaining. As was said above, the paralysis was of the peripheral type, and there was absolutely no local cause, such as otitis or trauma. Possibly the patient may have had grippe, or a slight rheumatic diathesis may have been responsible.

There is, of course, no reason why, in cases of facial paralysis due to a distinct neuritis, both nerves should not be involved; in fact, it is hard to explain why only a single nerve becomes involved in cases of neuritis supposedly due to some general systemic cause. However this may be, double facial paralysis is a rare occurrence.

A CASE OF GLANDULAR FEVER IN AN ADULT.

By ABRAHAM MAYER, M.D.,

NEW YORK.

Since Pfeiffer, in 1899, first described the affection known as glandular fever (*Druesenfieber*), little has been written which has added anything to our knowledge of this disease. In this country J. Park West in 1896, in an excellent article in the *Archives of Pediatrics*, described an extensive epidemic occurring in a small hamlet in Ohio, where ninety-six cases occurred in forty-six families, all between the ages of seven months and thirteen years. Dawson Williams describes the disease in Volume XIV. of the "Twentieth Century Practice of Medicine," and is also the author of a similar article in Allbutt's "System." On account of the scanty literature on this subject, it seems well to collect and report observations on cases which may come under our notice. This is the more important as the etiology of this affection is still obscure, and the classification still unsettled.

Of the various observers of this affection, Heubner, von Starck, Rauchfuss, and Hesse consider it a special infectious disease of benign character, while others have doubted the existence of this disease *per se*. Faidherbe, in a recent article in the *Bulletin de la Société Scientifique de Bruxelles*, considers it an unusual form of influenza. It has also been suggested that it may belong to the exanthemata, in which the eruption is absent. But as the symptoms are of the classical kind generally seen with infections, we may at least consider it an infectious malady due to the invasion of some micro-organism, the nature of which, be it staphylococci, streptococci, bacilli, or an organism *sui generis*, has not yet been determined. Bacteriological examinations have been made, but nothing definite has been found as the etiological factor. It is a specific disease, and its clinical syndrome, in the absence of evidence of other specific affections, stamps it as distinct in itself. Its sudden onset with headache, malaise, sometimes vomiting, constipation, etc., and rise of temperature—these symptoms in connection with enlargement of special glands characterize it as an acute infectious fever. It is at least reasonable to consider it such, rather than an obscure affection associated with enlargement of cervical glands. It affects children usually under the age of thirteen years; rarely adults. The lymph glands most commonly affected are those beneath and in front of the sterno-mastoid muscle; occasionally the axillary, in-

guinal, and mesenteric glands become the seat of an adenitis. Pharyngitis or tonsillitis rarely is present. In most cases no local conditions are evident, which makes the theory a fact that the enlargement of the cervical glands is due to an infection from the mucous membrane of the mouth or pharynx. Nor have investigations proved that the enlargement of mesenteric glands sometimes found in these cases is due to an infection from the bowels. This would lead one to believe that the adenitis seems to be the primary lesion, since it has not yet been established where the true porta invasionis lies. Although the relationship of clinical symptoms of this fever to other diseases of an infectious character must be considered, and notwithstanding evidence to the contrary, the early infection of the anterior cervical lymphatic glands makes it probable that the infection first finds its seat of entrance through the mucous membrane of the mouth or pharynx. This was exemplified partially in the case about to be described, in which a culture from the throat exhibited streptococci. It has been noticed that in most cases constipation was a prominent symptom in the onset, and von Starck suggested that the primary seat of infection was in the intestines whence the toxins were absorbed, and the mesenteric glands were the first to become enlarged; and from here the infective agent travelled through the thoracic duct and at its termination on the left side affected the lymphatic glands there sooner than on the right side. This latter conjecture was advocated by Koplik. It is logical and reasonable to assume that such may be the case, just as clinical experience has shown that often in an acute osteomyelitis the premonitory symptoms pointed to the gastro-intestinal canal as the porta invasionis (Kocher).

All observers agree that the disease is rare in adults. It has been my good fortune to observe a typical severe case in a young lady during the fall of 1899, Miss X——, blonde, twenty years old, family history exceptionally good. The patient suffered few of the ills of childhood and had never been sick until November 28, 1899. On the day in question she was suddenly seized with a severe headache and chill which forced her to go to bed. Her temperature rose within twenty-four hours to 104° F., pulse correspondingly high, over 100. She had nausea, vomiting, and anorexia; the tongue was not coated; she was constipated. There was no pain anywhere except a slight rigidity of the neck. The pharynx was only slightly reddened, otherwise the mouth and throat were normal. These symptoms continued for several days, and the aspect and condition of the patient suggested a commencing typhoid. The urine showed a trace of albumin, but no kidney elements. About the fourth day a glandular enlargement was noticed on the left side of the neck, in front of the sterno-mastoid muscle. The following day two or more glands on the same side became involved, with great stiffness of the neck. There was complete loss of appetite. The temperature was 103° F. The neck was extremely sensitive; there was pain on palpation, and the pressure on the surrounding parts caused pain on movement and consequently stiffness of the head. The spleen was much enlarged, the liver only slightly so. Except the above-mentioned symptoms there was nothing to indicate the nature of the disease. The blood had been examined up to this stage (the sixth day of the disease) four or five times, and with the exception noted below nothing abnormal was found. Various specimens were examined for Widal reaction, with negative results. Cultures from the throat were constantly being made, one of which showed the presence of streptococci. There was slight cough without expectation. No abdominal tenderness was present, and as far as could be judged from repeated examinations there was no involvement of the mesenteric glands; but constipation was marked and the bowels had to be moved daily by enemata. These symptoms lasted about seven days, with a gradual amelioration and decline of temperature. On the eighth day the glands on the right side of the neck became perceptible. There was again an increase of temperature to 103° F., and a more decided enlargement of the spleen, which was now painful on palpation. A solitary gland at the angle of the jaw on the right side was decidedly enlarged and caused excessive pain.

Successive involvement of different glands of the neck prolonged the pyrexia (which was of an irregular type) and also the other symptoms for several weeks until January 20, 1900, when the temperature first became normal and remained so. During the course of the disease the highest temperature recorded was when the glands reached their maximum enlargement; the last two weeks showed a range of temperature between 100° and 101.5° F. The pulse was rapid during the height of the fever, and was seldom below 80. The complications noticed were a slight cough in the beginning of the disease, which lasted a few days, and a slight albuminuria which cleared up in a week. But there ensued a gradual and continued constitutional depression and a rather decided anæmia. At the end of the fifth week of the disease an anæmic murmur was heard at the apex, which extended toward the base of the heart. The blood, which had been repeatedly examined, showed the proportion of red to white cells to be normal; but the eosinophiles were trebled in number, were larger than usual, and their granulations were coarser. The erythrocytes were pale and exhibited a deficiency of hæmoglobin.

In making a diagnosis of this case I was puzzled at first, and only by taking into consideration the history and circumstances of the case could a positive diagnosis be made. I had to exclude a secondary adenitis from lesions of the tonsils and pharynx, typhoid fever, tuberculosis, and specific infection. The treatment of the case had been purely symptomatic and sustaining. Nothing seemed to affect the course of the disease.

The total duration of the disease was eight weeks, and convalescence, once begun, continued uninterruptedly, and the enlargement of glands, spleen, and liver gradually disappeared.

After the case was recognized as one of glandular fever, repeated cultures were made from secretions of the throat and blood in hopes of finding a specific organism. Unfortunately they all proved negative with the exception of a single culture from the throat which showed the presence of streptococci. It appeared not unlikely that the micro-organism of this disease would be found in the glands affected. I am sorry to say that a bacteriological examination of the infected glandular tissue was not permitted. No fatal case of this disease has yet been reported.

40 East Sixtieth Street.

PLACENTA PRÆVIA WITH TWINS.

By M. F. HUSSEY, M.D.,
SIDNEY, OHIO.

In the Medical Record of June 2d, there was an article on placenta prævia with twins. Owing to the rarity of it, I desire to add one to the four or five other cases on record.

The case occurred in the practice of Dr. Peebles, of Hardin, Ohio, June 28th, but as the latter had at that time a case of puerperal sepsis under his care, he referred the case without examination to me.

Mrs. T——, aged thirty-five years, is the mother of six living children, all of whose births were normal. She menstruated last on November 1, 1899. During

the present pregnancy she was as well as usual, doing her own work. June 13th, without warning she had a slight hemorrhage. She gave but little attention to this, and next day resumed her domestic duties. On June 25th she had another hemorrhage, more severe than the last, but again the next day resumed her work. On June 28th, while she was in the garden, a severe bleeding started with so much severity as to cause her to take to bed and send for a physician. When I arrived I found her seemingly almost bloodless. There had been no hemorrhage for some little while before my arrival. Upon examination I found a marginal adherent placenta on the left side. I sent immediately for Dr. Peebles, with the request that he disinfect himself and hasten to my aid. I remained constantly with the patient until his arrival, during which time I had used my fingers as dilators, controlling the flow.

We pierced the placenta and ruptured the membranes. The head came down, stopping all hemorrhage. The birth of the first child was followed immediately by the breech of the second one, with but very little flooding. Both children were dead. The woman made an uneventful recovery.

Medical Items.

Character of Modern Chinese.—The following by no means flattering estimate of the Chinese character is given by one who has lived in their country for years and should, therefore, be qualified to judge. He says: "The modern Chinaman we know is the most selfish of mankind, callous as an animal, with only a relic of conscience; disinclined to fight because he thinks of himself first, and utterly corruptible because money is to him the supreme protection; but nevertheless a strong man with a clear head for affairs and with a strong faith, though it is in his civilization and not in any creed . . . He is the most accomplished liar in the world, but he does not love lying as a Hindoo does as a pleasurable intellectual excitement, but lies exactly up to the point where, as his native shrewdness tells him, lying is convenient for his interests."

Lepers in France.—It is estimated that there are about four hundred lepers in France, many of whom are missionaries and nurses who have contracted the disease caring for sufferers in distant countries, and also soldiers and officials from the colonies. They are now scattered about in Brittany, in the Pyrenees, on the shores of the Mediterranean, and in Paris, where there are one hundred and fifty. A committee has been formed at the instigation of Dom Santon, a member of the Benedictine community of Liguge, and also a doctor of medicine, to further measures for the care of lepers in France, and to prevent further spread of the disease. Dom Santon has studied leprosy for a number of years in the course of his travels about the world for this purpose, and his plans to deal with the disease in France have received the approval of the French government. He has acquired property in the Vosges, where he purposes to establish an asylum for lepers, to be called the St. Martin Sanatorium.

British Army Medical Report for 1898.—The London *Times*, in reference to this report, says: "As usual the annual report on the health and sanitary condition of the army loses much of its interest and value by reason of its belated appearance. There seems no sufficient reason for the double delay which occurs in forwarding the report from the medical division of the War Office to the secretary of state for war and in subsequently passing it through the press. Apart from this the report is full of interest and on the whole may be classed as satisfactory. Taking the average strength of the European troops at home and abroad as 202,166, the returns show a ratio of 9,819 admissions to hospital per 1,000 strength, on a strength of 203,980 which includes detached men not shown in the returns the death rate is 10.82 per 1,000. Among the troops in the United Kingdom the admission and mortality rates were somewhat higher than in 1897, but compare favorably with the average of the previous ten years. The chief point noted is the increase in enteric fever owing to the Khartum expedition, ninety cases and ten deaths having occurred after the arrival home of the troops. In Canada the ratios of sickness were much higher than in 1897, but in the West Indies there was a marked improvement, no cases of yellow fever having been recorded and venereal affections being much less prevalent. The latter remark applies also to South Africa, where the general ratios of sickness and mortality differed but little from those of the previous year and the average of the previous decade. Enteric fever was very prevalent, assuming epidemic proportions in Natal, where there was also much sickness from dysentery. In China there was a marked decline in malarial fevers. Plague, which was epidemic among the civil population, only caused eight admissions and one death among the troops. In India there was a decline in the admission and 'constantly sick' rates. The chief causes of sickness were as usual malarial fevers and venereal diseases, which together caused 55.4 per cent. of the admissions from all causes. Malarial fevers and enteric fever were more prevalent, but the admission rates for cholera, dysentery, and malarial disease were less than in 1897, the decline in venereal disease being equal to more than one-quarter of the ratio for the previous year. There were again a few cases of plague in the Bombay command."

Summer Mortality.—*The Evening Post* recently published the following, dated Albany, July 30th: "An article contained in a bulletin just issued by the State board of health furnishes some instructive data on the subject of summer mortality. The summer months in New York State appear to be the unhealthy season of the year. According to the State board of health's bulletin, the summer months show in addition to a large total mortality a great relative preponderance of mortality from the sometimes called preventable diseases and of deaths in early life. Of the local diseases the deaths reported from diseases of the digestive organs are increased. Diseases of the nervous system have a larger mortality than in the autumn and less than in spring and winter. Consumption has fewer deaths in summer. Cancer showed no maternal variation. There are fewer deaths from old age in summer. The deaths from accidents and violence are much increased, thirty-three per cent. occurring in these months; the increase is chiefly due to drowning and the effects of heat."

Hospitals in Roumania.—In the *Archives Orientales de Médecine et de Chirurgie* Dr. Cosma de Ploiesti gives some statistics which appear to show that Roumania is more liberally supplied with hospitals than are most countries of larger size. For a total population of 5,000,000 there are 188 hospitals with an aggregate number of 7,334 beds. All patients are treated gratuitously without distinction of nationality, and the foreigners from neighboring countries admitted every year to the hospitals of Roumania are numbered by thousands. The hospitals are kept up by the state or by the communes, or by the private administrative bodies, called "ephorias," which manage special funds bequeathed by charitable persons. The hos-

pital establishments are subdivided as follows: 53 departmental or district hospitals, with 1,355 beds; 26 communal hospitals, with 756 beds; 33 rural hospitals, with 1,602 beds; 10 belonging to the Bucharest ephoria, with 1,016 beds; 11 under the Jassy ephoria, with 683 beds; 10 maintained out of private funds, with 591 beds; 11 maintained by Jewish communities, with 289 beds; 5 lunatic asylums, with 749 beds; 11 homes for the infirm, with 405 beds; 1 hospital for sufferers from pellagra, with 40 beds; 16 homes for aged, with 324 beds; 2 night refuges, with 60 beds. In addition to these there are 6 nursing-homes, with 137 beds, for paying patients.—*British Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the surgeon-general of the United States Marine-Hospital service during the week ended August 4, 1900:

		Cases.	Deaths.
Smallpox—United States.			
Alaska, Cape Nome	July 1st.	17

The British Soldier's Daily Diet.—In *Pearson's Magazine* for May an account is given of the daily rations of the British soldier. They are as follows: One pound of fresh, salt, or preserved meat; one and one-quarter pounds of bread, or one pound of biscuit, or one pound of flour; one-sixth of an ounce of tea, one-third of an ounce of coffee, three ounces of sugar, four ounces of jam, one-half an ounce of salt, one-thirty-sixth of an ounce of pepper, one-half a pound of fresh vegetables, when procurable, or one pound of compressed vegetables, one three-hundred-and-twentieth of a gallon of lime juice, with one-quarter of an ounce of sugar, on days when fresh vegetables are not issued; one-half of a gill of rum, at the discretion of the general commanding, on the recommendation of the medical officer. Beer is not issued to troops on service, but tobacco is provided on payment. Careful calculations given the writer by a high official in the War Office reveal that the 200,000 who are being fed at the time of writing on home provisions consume in six months 16,000 tons of preserved meats, 16,000 tons of biscuit, 170 tons of tea, 3,000 tons of sugar, 340 tons of coffee, 4,000 tons of jam, 500 tons of salt, 30 tons of pepper, 8,000 tons of vegetables.

Julian Ralph on the British Army Scandals in South Africa.—Julian Ralph says in the London *Daily Mail*: "I am able to bear out much of the worst Mr. Burdett-Coutts has written about the sick and wounded with the army in South Africa. All, however, tend to confirm the results of his experience. In Bloemfontein there were twenty-five hundred enteric patients when I left, and they were in a large proportion left to lie on the ground and be nursed by ignorant and slovenly 'Tommy' attendants. They lay in the water, they were rained on, and the sanitary arrangements were such that, at least in some hospitals, they had to leave their blankets at the risk of death. All the time I was at Bloemfontein I was haunted by the horror of the neglect of and cruelty to the sick. When I was at Kimberley, some of the local physicians were similarly horror-stricken by the condition in which the wounded came to them, trundled over the bad roads all the way from Paardeberg in ox wagons. I have no hesitation in saying that I considered the treatment of the sick and wounded (especially after the main advance from Modder River) primitive, cruel, and almost barbaric, as well as needless and inexusable."

EXTRABUCCAL FEEDING.[1]

BY C. A. EWALD, M.D.,

BERLIN.

EVERY disease of the digestive system making the administration of food by the natural channel impossible, or in which the assimilation of the ingesta is impaired to a greater or less degree, confronts the physician with the question whether it is not possible by some other avenue to supply the organism with sufficient nutriment to sustain life and to rehabilitate the damaged nutrition.

This is not the place for an enumeration of the various conditions which may result in such a state of restricted receptive power or imperfect food absorption. The methods of feeding through the œsophagus by means of the stomach-tube also lie outside the limits of the present discussion. It is a question rather of (1) rectal feeding by means of nutritive enemata; (2) feeding through the cutaneous surface by means of subcutaneous or intravenous injections of food stuffs; and (3) feeding after gastrostomy.

While so-called nutrient enemata, *clysmata nutrienta*, have been used by the profession of old, although very different degrees of value have been accorded them by individual physicians and in different times, the two latter procedures are distinctly productions of later date.

At the outset of my discussion I must premise, that none of the above-mentioned means is capable of supporting life indefinitely, and that under no circumstances can any of them be regarded as able to answer the demands of the metabolism of the normal healthy individual. Under favorable circumstances it is possible through the exclusive use of extrabuccal feeding to maintain for some time the nutritive balance of those who in consequence of their sickness exhibit a greatly decreased metabolic activity, in other words those in a very much depreciated physical condition, as I years ago demonstrated by experiment.[2]

In most instances, however, a state of under-nutrition supervenes, in which the body gives off more than it receives through the medium of the extrabuccal feeding. The result of the measure is therefore merely to reduce this deficit to a smaller margin than would otherwise be the case, and, furthermore, it is only a question of a temporary expedient and not of a permanent form of feeding. Therefore the method is of real value only in those cases in which it plays the part of makeshift, tiding the patient over certain critical stages of his disease, or when it is resorted to for some definite therapeutic purpose, as in the treatment of gastric ulcer, hysterical vomiting, dilated stomach, etc., or when employed as "supplementary feeding" in cases of deficient nutrition per os. In other cases one must rest satisfied with having prolonged life for a certain length of time and with its effect of affording the patient some degree of moral comfort.

I. Rectal Feeding.—It may safely be accepted that the secretion of the large intestine is devoid of all peptonizing power and possesses only very slight amylolytic properties. Hemmeter[1] has shown that the aqueous extract of the rectal contents obtained under aseptic precautions is capable, in weakly alkaline solution, of dissolving 36.5–50 per cent. of dried serum albumin in three hours and of converting as much as fifteen per cent. of starch into maltose, but is without steatolytic power. Nevertheless, these properties of the fæces, inasmuch as the action of bacteria was excluded in Hemmeter's experiments, are ascribable solely to the admixture of pancreatic juice which at different times and under various conditions is probably a very variable quantity. As it is customary, however, before the administration of nutritive enemata to cleanse the rectum, this ferment component of the fæces cannot enter into the question. There are to be considered, therefore, only those quantities of pancreatic juice which trickle down to the enema during its sojourn in the intestine, and the effect of the intestinal bacteria which, to be sure, exhibit a certain amount of albumin-splitting power. The production of the Leube-Rosenthal "pancreatic-meat enemata" through the addition of pancreatic-tissue substance to the albumin was only the logical outcome of the formerly prevalent idea that for absorption through the rectal mucosa a previous peptonization of the albumin and conversion of the starch was requisite. Experiment showed that almost the entire amount of nitrogen supplied to the body in the "meat-pancreatic enemata" was absorbed.

Still it must not be disregarded that the preparation and application of such mixtures are inconvenient for both the physician and patient. From personal experience I know that the obtaining of the gland substance and the proper preparation of the mass to be employed in the enemata both present difficulties that, especially in private practice, are not easily overcome. The temptation was therefore great, in view of the advances that had been made in the commercial production of artificial foods and soluble peptone and albumose preparations, to employ these instead of the "pancreatic-meat" mixture. No doubt this has been widely done without attracting especial comment; at any rate I myself have frequently made use of such peptone and albumose solutions, and particularly as additions to the egg-enemata to be described below.

Contrary to a statement of v. Leube's,[2] however, I must observe that even small quantities of peptone, *i.e.*, 50–60 gm. dissolved in 200–250 gm. of water, occasionally produce marked evidence of irritation and are speedily expelled. Still this apparently depends somewhat on the nature of the peptone, for I have noticed that peptones of different sorts behave differently in this respect. This much is certain, that according to my experience peptone solutions are well absorbed and can cause an excretion of nitrogen, and

that Kohlenberger[1] and von Leube never found albumose or peptone in the urine after the administration of such enemata, a proof that these bodies had actually undergone metabolic transformation.

The composition of nutritive enemata was greatly simplified after Eichhorst's[2] experiments on the dog and mine on man had shown that even native albumin in the form of egg emulsion and the casein of milk was absorbable without preliminary peptonization. The absorbability is greatly increased, as Eichhorst had already found, by the addition of table-salt. In the light of these facts, which have been fully substantiated by later observations of my own and others, the use of albumose and peptone preparations has fallen more and more into disrepute until at present they are hardly employed at all.

As a matter of fact, the esteem in which peptones are held as constituents of nutrient enemata rests, as I maintained in 1887,[3] on the setting up of a fallacious analogy with the conditions obtaining in the stomach. While we supply this viscus, when it is diseased and impaired in function, with peptones and albumoses with the (at present also contested) intention of relieving it of a portion of its work, we should never think of treating the rectal mucous membrane, no matter how much diseased, in a similar way.

Here we have to do with a healthy mucous membrane which is to assume the functions of the higher portions of the digestive tract. Inasmuch as my observations have given evidence that the peptonization of albumin or the use of the peptones on the market is not needed for absorption from the rectal mucosa, and that this itself cannot convert albumin into albumose or absorb it in other ways, the employment of peptone enemata becomes unnecessary. Simple egg enemata accomplish just as much, and in addition furnish about twelve per cent. of fat, which effects a saving to the organism through its fuel value.

Only in later times has the fact of albumin absorption in the colon met with controversy. Plantenga[4] has published a series of experiments yielding very unfavorable results regarding the absorptive power of this membrane for nitrogenous bodies. In one instance in which 70 gm. of nitrogen was administered per rectum during the course of the observation, an average of only 0.375 gm. per day was absorbed, and in another in four days only 1.43 gm. was taken up.

I have, therefore, had a new series of investigations made by Rost, which have confirmed the old dictum that very considerable amounts of the nitrogenous substances administered by the rectum, under favorable conditions ninety to ninety-five per cent., are absorbed.[5]

At this juncture the query might arise whether we are actually dealing in these cases with an absorption of albumin or nitrogenous substances of actual service in the economy of the organism, or whether the nitrogen reappearing in the urine does not represent further decomposition and putrefactive products of ammoniacal nature found in the urine. This seems to me not to merit consideration, since it is never possible to find considerable amounts of ammonia in the expelled portions of the enemata by means of the Schlössing method, and a well-marked odor of putrefaction is present only in the fewest cases. Besides, it is possible to anticipate any such fermentative change by the addition to the enema of small amounts (0.1–0.3 gm. to each injection) of some such substances as thymol, menthol, or lysol. Like the soluble egg-albumen the albumin of milk also undergoes absorption. Experiments on the value of milk for this purpose were conducted by Eichhorst as long as thirty years ago, but Brandenburg[1] has lately shown that more than one-third of the casein of milk is never absorbed, and von Leube justly says that even in relatively large quantities, one-half litre of milk to the enema, under the most favorable conditions hardly 100 calories are taken up, and even this only under the supposition that complete absorption of the carbohydrates takes place. But the probabilities are that the actually effective amount is appreciably smaller than this.

Of late, as is well known, a number of preparations have been put upon the market which contain the albumin in part converted into albumoses, in part in an undecomposed but readily soluble state. These preparations do not present any especial advantages for the preparation of nutritive enemata. They irritate the intestinal mucosa, and, according to the researches of Kuhn and Völker, Brandenburg, Strauss, and others undergo imperfect absorption, so that up to sixty per cent. of the material employed remains unused.

As regards the nitrogenous bodies we are therefore constantly driven to revert to the native egg-albumen and milk.

What now are the facts concerning the application of the carbohydrates in nutritive enemata?

Primarily, from physiological considerations solutions of grape sugar would be found to serve best, and the other varieties, especially cane sugar, should also be investigated, while enemata of starch decoction (flour paste) are less suitable for the purpose, since the advantage they possess, following von Leube, of causing a slow formation of sugar and a consequently diminished amount of irritation, is offset by the greater possibility of decomposition and fermentation induced by that very fact.

The experiments of Schönborn[2] have proved that very considerable quantities of grape sugar (up to ninety-five per cent.) may be absorbed from the intestine, but the solution must not be too concentrated nor be injected in too great quantity, otherwise irritation, diarrhœa, and the secretion of mucus are caused. This coincides with my own experience, and I recommended years ago that not more than 10–20 gm. of grape sugar, that is, about 100 c.c. of a corresponding solution, should be used. Whether cane sugar is absorbable to the same degree as glucose is a mooted point, but according to Plantenga it is less irritating. Lactose has been shown by Strauss[3] to be well absorbed and to be converted into grape sugar, though from a practical standpoint it hardly needs consideration.

In an overwhelming majority of cases the rectal injection of sugar solutions is not followed by the excretion of sugar in the urine. As Strauss has shown, the same relations obtain here as in the administration of the same amounts of grape sugar, etc., by the mouth. Since the hemorrhoidal veins empty their contents directly into the vena cava, thus excluding the liver and portal system, such a glycosuria is not to be discounted *a priori*. However, the results of my observations, read before the Naturforscherversammlung at Frankfort in 1896, taught the contrary, since as low as 6 to 7 cm. from the anal orifice there are anastomoses between the superior and middle hemorrhoidal veins through which blood reaches the portal vein.

Recently von Leube has shown that such a glycosuria may be produced if access to the upper part of the

rectum be cut off by the introduction of a colpeurynter before injection of the solution, and its absorption be therefore restricted to the inferior hemorrhoidal veins. The same observer has stated that breaking down into lactic acid, acetic acid, etc., through the growth of fungi does not occur to a noteworthy degree, for the absorption of the sugar takes place so rapidly (in the first hour from sixty to ninety per cent. of the injected amount) that no time is given for any appreciable decomposition.

Starch decoctions of twenty- to thirty-per-cent. strength yield approximately the same results as are obtained with sugar solutions. A portion of the starch, varying in different cases, is hydrolized and absorbed, while the remainder, amounting to from four to twenty-five per cent. of the total quantity, is expelled in an undigested state after a longer or shorter period of time. Evidences of irritation are less than with sugar injections, but are not wholly wanting.

It is in the administration of fats per rectum that the greatest difficulties are presented. Complementing the voluminous discussions of former times on the value of fats in the preparation of nutritive enemata the work of Dencher,[1] Stüve,[2] and Strauss[3] on injections of olive-oil emulsion has shown that under the most favorable conditions not more than 10 gm. a day can be absorbed. If, however, after the method of von Leube the fat is mixed with pancreatic-gland substance before its introduction, ninety per cent. or even more may be taken up. But here also there is no constant relationship, and especially the simultaneous administration of starch, fat, and pancreatic substance seems to be badly borne, premature expulsion of the enema resulting.

From what has been said it follows that in practice it is wisest to make use of all the food-stuffs in question, and to vary the composition of the enemata according to the exigencies of each individual case, that is, the degree of tolerance exhibited for their various components.

Guided by my extensive experience, I still believe that the following combination is the one to be most recommended: Two tablespoonfuls (40 gm.) of wheat flour are stirred into 150 c.c. of lukewarm water or milk, and to this mass one or two eggs with a pinch of salt (3 gm.) are added, and the whole is beaten up with 50 to 100 c.c. of a fifteen- to twenty-per-cent. glucose solution. The addition of a small amount of alcohol, *e.g.*, in the form of a glass of claret, acts as an analeptic. Such an enema corresponds to about 450 calories, of which, to be sure, only a portion fulfil their physiological destiny. It goes without saying that the nutritive value of such a combination may be increased by varying its constituents and adding some peptone preparation, for example, one of the newer food products, such as eulactol or plasmon. But it must not be forgotten that the more complicated the composition of an enema the greater the difficulty of its application in private practice, and the more probable the production of irritation of the intestinal mucosa and its early expulsion. Finally there remain to be mentioned the nutritive enemata in concentrated form consisting of suppositories of peptonized meat or peptonized milk.

The well-known method of administration of such enemata I shall not discuss. As in everything of this nature, a certain amount of practice is necessary, simple as the matter seems, and the more experienced the physician and nurse the longer will the enema be retained and the less discomfort will it cause.

II. Feeding by Means of Subcutaneous Infusion.—It is not to be denied that nutritive enemata do not fulfil all the demands we have to make on an extrabuccal method of feeding. Disregarding the variations in the actual nutritive effect produced, the irritative disturbances attendant on their long-continued use, and their impracticability in certain diseases of the gut itself and in persons mentally deranged, greatly limit their sphere of usefulness. There exists, therefore, a need for some other manœuvre which shall be free from these objections, and as such the intravenous and subcutaneous injection of food-stuffs is to be considered. It is particularly to von Leube that credit must be given in this regard, for it was he who, after various tentative efforts in this direction had been made, furnished the clinical and experimental evidence of the feasibility of the method.

As early as 1850 Hodder made intravenous injections of milk into cholera patients in collapse, and such injections and similar ones of peptone solution were in consequence often repeated, and with apparently favorable results. In addition subcutaneous injections of milk, peptonized milk, and defibrinated blood have been recommended and carried out.

At the very outset, however, it is clear that in such attempts the injection of every sort of albumin solution, either in the natural state or to a greater or less degree peptonized, must be avoided. The necessary sterilization is impossible, and on account of the well-known toxic effect of the albumoses and peptones they are useless for the purpose in view.

The subcutaneous injection of glucose solutions has also not given any encouraging results; persistent pain, even inflammation and necrosis, are said to be easily caused. Still Voit[1] did not observe any evil effects from the subcutaneous infusion of a ten-per-cent. glucose solution, of which up to 1 litre was thrown into the thigh within twenty to twenty-five minutes, and when given in small quantities it was found never to be excreted in the urine. Only after 100 gm. of sugar had been given was 2.6 gm. excreted by the kidneys. Since 100 gm. of sugar corresponds to 410 calories, that is, nearly a third of the amount required by a resting person in a depreciated state of health, such a result should be counted as a distinct gain. It is evident that if it were possible to infuse a like amount of oil a very much greater calorie value would accrue to the organism, for 50 gm. of oil corresponds to 465 calories, so that one might either use a less quantity of oil or by giving more contribute a considerably larger amount of fuel values.

Von Leube[2] has shown in repeated communications that this infusion of oil presents no technical difficulties, and has also proved by ingenious experimentation that the fat really is consumed. He injected butter in a state of solution into dogs and determined the following:

A dog, brought to a state of leanness by feeding on fat-free horse-meat, received in fifty days 3.50 kgm. of butter subcutaneously and in this time gained 2.4 kgm. The chemical examination of his abdominal fat showed this to consist of pure butter: the dorsal fat was one-third and the pericardial fat one-sixth butter. A second experiment was begun by doing a laparotomy on a fat-free dog, showing that the mesentery was almost and the skin entirely devoid of fat. In the course of the next three weeks he was given subcutaneously about 1,400 gm. of butter. A second laparotomy showed that the skin of the abdomen now contained abundant fat masses composed of two-thirds of butter and one-third of dog-fat, while the fat of the now richly adipose mesentery was almost pure dog-fat. The animal was now returned to his fat-free diet till

he gradually became reduced to his former weight. He was then killed and found to be absolutely fat-free.

The experiment, therefore, shows that a fat-free dog can be made to accumulate dog-fat through subcutaneous injections of butter, and that this may undergo complete metabolistic consumption. Further researches by Knoll [1] on rabbits demonstrated that the absorption of fat takes place slowly from the site of the injection, and that the albumin consumption is diminished in the usual way, the coefficient in an oil-treated animal being only about fifty per cent. of the corresponding value in a control animal.

The accuracy of these results has been confirmed in various quarters, and also by observations on man most comprehensively and carefully by Du Mesnil de Rochemond,[2] who lays great stress on slowness in the rate of injection of the oil, and has devised a somewhat complicated pressure apparatus for this purpose.

I myself make use of the following very simple method. I employ a large wash-bottle holding about 1 litre, such as is used in the sulphuretted-hydrogen apparatus, and consisting, as is well known, of a glass jar through whose upper constricted portion a glass tube passes air-tight to the bottom, while at the side a second horizontal tube is fused into place. If a rubber tube bearing a hollow needle with a lumen of about 1 mm. is affixed to the longer tube, and the horizontal one is connected to a double-acting bellows of good size, and 200–300 c.c. of oil placed in the jar, by the aid of the bellows the air contained in the flask may easily be compressed to such a degree that the oil is forced up the perpendicular tube and out through the rubber tubing and cannula. The rate of flow may be accurately controlled by means of a pinch-cock on the tube, and a scale affixed to the jar determines the amount of oil used. The apparatus may be readily taken apart for disinfection, and the air which is forced in does not come in contact with the lower layers of oil, though it might easily be purified by the interpolation of a small filter of cotton. I have never had occasion to do this, however. After having introduced the needle into the subcutaneous connective tissue under the usual antiseptic precautions the apparatus may be left at the patient's bedside without supervision; the pressure once established lasts for a half-hour or so, and may be regulated so that in this length of time 80–100 c.c. of oil enters the tissues.

Unfortunately the procedure is not entirely free from pain. A certain degree of tension and redness of the skin is caused, which lasts for hours even if the oil is diffused as much as possible by massage. Other inconveniences, such as abscess formation, necrosis, or fat embolism have not come under my observation; oil is not excreted in the urine.

Nevertheless the manœuvre involves troublesome preparations, and in sensitive individuals cannot be carried on for any length of time. Another disadvantage which places the oil injection below the nutrient enema in the scale of utility lies in the fact that by this means the introduction of water into the body is not possible. But this is a point of highest importance precisely in those cases in which extrabuccal feeding is indicated. For in this the administration of water per os is not possible, either because access to the stomach is cut off, or the dilated stomach is incapable of absorbing water, or finally it is speedily vomited. But the prevention of this diminution in water-supply is of great significance in these conditions, and as my pupil Dr. Rost [3] has shown, the supplying of water is sometimes even more necessary or at any rate just as important as the giving of food. Of course the possibility remains of giving nutrient enemata in connection with the oil injections, as von Leube has mentioned, but according to my experience it would be difficult to find patients willing to consent to this method more than once or twice.

In every-day practice, therefore, the nutrient enemata will have the advantage over the oil injections, especially as they do not offer the risk of infection which is always present with the latter.

III. Feeding Through the Gastric Fistula.—Since gastric fistulæ are made only under circumstances in which access to the stomach per vias naturales is permanently blocked, and every sort of fluid food may be introduced through the opening, it is in these cases not so much a question of the character of the nutritive mixture to be used as of whether its digestion and absorption by the stomach are possible. It is essential to consider the conditions which have made the establishment of the fistula necessary. In cases of benign cicatricial strictures of the œsophagus, the digestive function of the stomach is not materially impaired, and I have seen patients who continued in an excellent state of nutrition after the operation. If the matter injected through the fistula was again withdrawn after a suitable lapse of time, the normal alterations in character were recognizable.

Quite the reverse is the case when malignant new growths are in question. Here the functional activity of the stomach, as I must maintain contrary to other opinions, is wholly abrogated, and digestion takes place not in the stomach but only in the intestine. The use therefore of the native albumins and carbohydrates is not indicated, but it is preferable to employ the more or less predigested albumose and peptone preparations and glucose solutions, and to locate the fistula as near to the pylorus as possible, as I have already indicated in former years, so that it may be possible to introduce the food directly into the intestine by means of a tube passed through the gastrostomy wound. Unfortunately in most cases the conditions are so unfavorable that a protracted and satisfactory feeding cannot be accomplished.

Conclusions.—1. Extrabuccal feeding does not completely replace feeding by mouth, and is not permanently capable of answering the demands of metabolism. In most cases in which this method exclusively is resorted to a state of malnutrition sets in from the outset. An exception to this rule occurs in those cases of gastric fistula in which the operation was necessitated by a benign stricture of the œsophagus.

2. For a short time, in weakened individuals whose metabolism is below normal, it may be possible through extrabuccal feeding to increase the nitrogen conversion and even to cause an accumulation of nitrogenous substance and fat.

3. The best results are obtained when it is a question of a temporary replacement of the natural feeding per os, or when extrabuccal feeding is resorted to as an accessory measure to the former.

4. Nutritive enemata are to be preferred to the subcutaneous injection of oil. The applicability of the latter lies rather in isolated cases than as a measure adapted to widespread use in practice.

Luxation of the Acromion.—Bore directly through the acromion with the longest and strongest drill at hand, and also bore lengthwise into the clavicle a distance of 5 cm. The drill is left in for eighteen days, the apparatus holding the bones in normal position during the drilling having been removed.—K. BÜDINGER.

MIGRATED OVARIAN AND PAROVARIAN TUMORS.[1]

By GEORGE M. EDEBOHLS, A.M., M.D.,
NEW YORK.

By migrated ovarian and parovarian tumors we understand such growths as have become entirely detached from their former connection with the broad ligament, and which either lie free in the peritoneal cavity or are united by new attachments to organs and tissues other than those from which they were originally derived.

Various names have been proposed for this class of tumors. Migratory and migrant, the latter suggested by Stone, denote emigration not as yet completed, and consequently do not correspond with the condition usually encountered. Almost equally with the terms wandering, errant, and vagrant, they might be made to apply to a tumor with a very long pedicle permitting of extensive excursions. The term parasitic has long been pre-empted for tumors due to parasites, and this pre-emption should be respected. To call them ectopic tumors would tend to confusion with tumors due to extra-uterine fœtation. They are often designated as detached tumors, but this term applies, strictly speaking, only in those exceptional instances in which the tumor lies entirely free in the peritoneal cavity. Of the more admissible designations, such as alien, expatriated, exiled, transplanted, self-amputated, and migrated tumors, I prefer the last named.

Torsion of the pedicle of the tumor up to complete strangulation and division, with implantation of the tumor upon neighboring organs, selectively and most frequently upon the omentum, either before, during, or after detachment from its original site, represents in the majority of instances the processes by which an ovarian or parovarian tumor qualifies as migrated. Tension or traction upon the pedicle no doubt frequently assists torsion in effecting complete separation, a combination of which forces I have seen active in one of my own cases.

As an outcome or final result of these processes, the ovary or ovarian or parovarian tumor occupies a new habitat, while the adnexa of the corresponding side are generally represented by a more or less short stump of Fallopian tube and ovarian ligament which remains attached to the uterine cornu. The Fallopian tube and ovarian ligament may, on the other hand, be twisted or pulled in their entirety out of the uterus, so that the differentiation between congenital aplasia of the uterine adnexa on the one hand and their disappearance as a result of pathological processes on the other may become very difficult, or even impossible. In doubtful cases the determination of the presence or absence of the interstitial part of the tube may be needed to decide the question. Braun,[2] as quoted by Kossmann,[3] describes and pictures a case of complete detachment of the ovary in which, after the lapse of a few years, all trace of a scar or other indication of the former site of attachment had disappeared from the broad ligament. In my own Case II. detailed below, the same result has by this time undoubtedly obtained.

That the new pedicle of attachment of a migrated ovarian tumor is liable to the same accidents of torsion and rupture as the original pedicle is shown by the case of Chalot.

Stone[4] and Coe[5] have recently well covered the subjects denoted by the titles of their respective articles. The present paper is offered more as a clinical contribution, since I find myself in a position to add four further cases to the hitherto reported twenty-five or thirty cases operated upon for migrated ovarian or parovarian tumors. My own cases, perhaps, in addition to furnishing the largest individual contribution to the subject, possess the merit of having been more closely observed and of being more accurately described than the majority of those reported. I have no doubt, however, that there are on the note-books of a considerable number of operators records of similar experiences, the publication of which may be stimulated, as has obtained in my own instance, by the recent papers of Stone and Coe.

Case I.—Gangrenous monocyst, presenting all the characteristics of a migrated parovarian cyst, removed from the omentum by operation; cure. Mrs. M. E. F——, aged thirty-seven years, married, a patient of Dr. G. J. Moser, was admitted to St. Francis Hospital, April 20, 1893, suffering from a painful, fluctuating, globular tumor, 20 cm. in diameter, located in the central part of the abdomen, immediately behind the umbilicus. The uterus and right adnexa, normal in size, could be palpated below the tumor; the left adnexa could not be recognized. Cœliotomy, April 21, 1893, revealed a monocyst, presenting all the characteristics of a parovarian cyst, attached by a pedicle 10 cm. wide and 2 cm. thick to the lower free edge of the omentum. There were no other attachments whatsoever. The contents of the cyst, a bloody, grumous fluid, measuring two litres, were evacuated; the omentum pedicle was tied off and the cyst removed. The cyst wall opposite the attachment to the omentum was gangrenous over a circular area 15 cm. in diameter, and the inner layers of the cyst were studded with innumerable points of ecchymosis. The uterus, both tubes, and ovaries were found perfectly normal. The abdomen was cleaned and closed without drainage. There were uneventful convalescence and primary union. She left the hospital May 10, 1893, and has remained well to date.

I have classed this tumor as a migrated parovarian cyst because it presented all the characteristics of the latter and none of those common to tumors originating in the omentum. The fact that the uterus and tubes presented nothing abnormal does not militate against my view of the case, since Braun has shown, and my own experience bears him out, that an ovary may be twisted off and leave no trace to indicate the site of its former attachment to the broad ligament.

The detachment of a parovarian cyst, leaving intact the tube and ovary of the same side, can be readily understood. That a parovarian cyst, however, in twisting itself free, may carry with it the tube and ovary of the same side, is proven by the following case:

Case II.—Large, strangulated left parovarian cystoma free in the abdominal cavity, its pedicle having just been completely severed by torsion; left ovarian ligament and left Fallopian tube completely pulled out of uterine cornu; coexistence of umbilical hernia; parovariotomy and radical herniotomy; cure. T. H——, aged thirty-three years, single, came under observation March 26, 1892. For a year previously she had known of an abdominal enlargement, which had caused her no special annoyance or apprehension until within the past two days, during which she has suffered from persistent abdominal pains, vomiting, rapid pulse, and slight elevation of temperature.

Examination showed a globular, sensitive, elastic tumor filling the lower half of the abdomen from pubis to umbilicus. The tumor displaced the uterus downward and backward, and although situated mainly on the right side appeared to be connected by a thick, tense band with the left adnexa. The diagnosis was made of strangulated left ovarian cystoma. Tempera-

ture, 101° F.; pulse, 100. A large umbilical hernia was also present.

The operation was done at St. Francis Hospital, March 28, 1892, four days after the commencement of symptoms of strangulation of the cyst. On incision of the abdomen a black cyst presented, with its rather thick walls still unruptured, though uniformly purplish-black from incipient gangrene and diffuse extravasations of blood. The peritoneal cavity in the neighborhood of the pedicle of the tumor contained about 100 gm. of fluid blood and clots which were mopped out. The cyst was punctured and one litre of port-wine-colored, bloody fluid was drawn off by aspiration. Further exploration showed the cyst to be entirely free, having no attachments whatsoever. The stump of its former pedicle, which still remained attached to the left inferior aspect of the cyst wall, was in a strangulated condition, deep black, friable, and contained in its substance blood clots in beginning disintegration. The free blood in the peritoneal cavity came from the ruptured pedicle which was still in condition and position to demonstrate at least two complete twists, from left to right, upon its own axis. The left tube and the left ovarian ligament were completely torn out of the cornu of the uterus, leaving no vestige there of their former presence. The entire left tube and the left ovary were found in beginning disintegration in the stump of the pedicle of the self-amputated cyst. The right ovary and tube were perfectly normal. Tension or stretching of the pedicle no doubt greatly aided torsion in effecting complete separation; the tumor, although originating from the left parovarium, being locked in the right half of the abdomen by spastic contraction of the recti abdominis muscles. The peritoneal investment of the intestines as well as of the parietes adjacent to the tumor showed signs of incipient inflammation with plastic deposits. After thorough mopping with damp sublimate gauze, the abdominal incision was extended upward to embrace the umbilical hernia. Radical herniotomy was done, with complete closure of the abdomen without drainage. There was an uneventful convalescence; primary union took place. She was discharged from the hospital three weeks after operation.

Remarks: Had the patient survived without operation, the incipient peritonitis would probably have provided for the attachment and continued sustenance of the tumor separated from its original source of nutrition. Possibly the cyst contents would have escaped, after rupture of the cyst wall, and have been absorbed by the peritoneum. The cyst wall itself might have disappeared by absorption or organic incorporation with the adjacent parts, or by both these processes combined. An abdominal section or an autopsy after these changes were completed would have demonstrated entire absence of the left ovary and tube. All of which goes to show that complete absence of one ovary and tube may be the result of self-amputation as well as of congenital aplasia, and that the diagnosis of the latter condition is not, as has heretofore been assumed, unequivocally established by finding no vestige of the tube and ovary of one side.

Case III.—Self-amputation of left ovarian cyst and tube; intraligamentous right ovarian cystoma; chronic metritis and appendicitis; cœlio-oöphoro-salpingo-hysterectomy, inversion of appendix; cure. E. S——, aged thirty-six years, married, mother of five children, was admitted to St. Francis Hospital, May 24, 1898, with a history of atypical metrorrhagia, leucorrhœa, bearing-down sensations, and dyspareunia. Examination showed chronic metritis, a tumor about 8 cm. in diameter of the right ovary, chronic appendicitis, movable right and left kidneys.

Operation was done May 27, 1898. When the abdomen was opened there were found a large and heavy uterus, an intraligamentous right ovarian cystoma, hen's egg in size, and far advanced appendicitis obliterans. The left ovary was entirely absent; the left tube also being missing, with the exception of a twisted stump, 2 or 3 cm. long, which remained attached to the uterine cornu. The free end of the twisted tubal stump was sealed and smoothly rounded. The left round ligament was intact. Attached to the entire posterior aspect of the uterus and to a portion of the left broad ligament was a firm membrane of irregular thickness, which on subsequent examination proved to be part of the sac of a former left ovarian cyst. The operation consisted of excision of the uterus, right ovarian cyst, right tube, and stump of the left tube, with inversion of the vermiform appendix. Complete closure was done without drainage. There was uneventful convalescence; primary union took place. She was discharged well, June 22, 1898.

Remarks: The conditions found and described above leave no doubt that a former left ovarian cyst had at some time twisted itself free, carrying with it the greater part of the left tube. The cyst contents had escaped and been absorbed together with a part of the cyst wall. The remainder of the cyst wall had become adherent to the back of the uterus and left broad ligament, and had thus maintained its vitality. There was nothing in the patient's history to indicate at what period of life the self-amputation of the left ovarian cyst had occurred. The period of occurrence of a like event, however, was well marked in the history of the next case.

Case IV.—Migrated dermoid of right ovary; left ovarian cystoma; bilateral ovariotomy; amputation of omentum; inversion of appendix; cure. E. A——, aged thirty-six years, married, never pregnant, was sent to me by Dr. Dayton L. Kathan, of Schenectady, N. Y. The only events of importance in her previous history were two attacks of acute peritonitis, the first twelve and the second ten years ago, each attack having confined her to bed for five weeks. With these exceptions she was well until about a year ago, since when she had noticed progressive enlargement of the abdomen.

Examination showed a normal-sized uterus doubled forward upon itself underneath a fluctuating tumor diagnosticated as an ovarian cystoma, the cyst enlarging the abdomen to a size and shape corresponding to a normal pregnancy near term.

Operation was performed May 29, 1897, at the Post-Graduate Hospital. When the abdomen was opened a large monocyst of the left ovary presented, and was tapped and removed. Further examination showed complete absence of the right ovary and of all but 2 cm. of the right tube, which with an equal length of the right ovarian ligament formed a stump attached to the right uterine cornu. The right round ligament was intact. The lower free end of the omentum was enormously thickened and wrapped completely around a tumor, 15 cm. in diameter, which proved to be a dermoid of the right ovary containing teeth, hair, and sebum. The dermoid had absolutely no other attachments except to the posterior surface of the omentum, which completely enveloped it and from which it received its sustenance by means of numerous small vessels, none of them large enough to require ligation. The tumor was simply peeled out of the omentum without any bleeding. The greater part of the hypertrophied omentum was removed by amputation, the appendix vermiformis inverted, and the abdomen closed. There was a smooth convalescence. She was discharged three weeks after operation.

Remarks: Torsion of the pedicle of the right ovarian dermoid without detachment probably occurred in the first attack of peritonitis twelve years previously, while complete detachment of the tumor coincided with the peritonitic attack of two years later. The tumor then became engrafted upon and drew its

further sustenance from the omentum, in which it was found completely wrapped.

I have collected from the literature and tabulated the following forty-three pertinent cases, fourteen of them referring to post-mortem findings, and twenty-nine observed on the operating-table:

I find in the literature one case each attributed to Amann, Jr., Boxall, Braun, Koeberlé, Pozzi, and Pulteney. Some of the references given I have found incorrect, and in the case of the remainder I do not happen to have access to the original publications. I have, therefore, preferred to omit altogether these cases, rather than to quote them at second-hand.

I append a summary of the above-noted cases of migrated ovaries and ovarian and parovarian tumors: 3 free ovaries, 1 right, 2 left; 3 parovarian cysts, 1 left, 2 side not stated; 21 ovarian cysts, 3 right, 12 left, 6 not stated; 15 ovarian dermoids, 5 right, 9 left, 1 not stated; 1 cystosarcoma of left ovary.

59 WEST FORTY-NINTH STREET.

POSTERIOR COLPOCŒLIOTOMY FOR LESIONS OF THE ADNEXA AND UTERUS; ITS INDICATION AND TECHNIQUE.[1]

BY CHARLES GREENE CUMSTON, M.D.,

BOSTON, MASS.

IN February of this year I had the honor of reading a paper on posterior colpotomy for acute suppurative lesions in the female pelvis, before the Gynæcological Section of the Suffolk District Medical Society, and on this occasion I would like to consider this excellent operation for the removal of diseased appendages and certain neoplastic productions of the uterus. I have always upheld that when an abdominal incision could be avoided, and still a thorough operation be done through the vagina, the latter should be the preferred route, and the experience of several years in vaginal work has led me to feel more strongly on this point than ever. I trust that these remarks, coming as they do from a general surgeon, and not a specialist, may be received kindly, and although in this paper the writer does not wish it to be understood that he believes the vaginal route is the only one to select in gynæcological cases, still he feels certain that many women may be relieved of their infirmities without going through the rest of their lives with a weak abdominal wall and a scar.

The vaginal route is at the present time no longer limited to simple puncture and drainage, or to total vaginal hysterectomy, and its field of usefulness has become extended for the treatment of a large number of pelvic lesions, thanks more especially to the modern and improved technique. In a recent and very excellent article on vaginal cœliotomy by Dr. J. Riddle Goffe, which appeared in the *Medical News* of October 7, 1899, this authority goes so far as to say that ninety per cent. of pelvic affections may be treated through the vagina, but this I believe to be somewhat of an exaggerated statement.

In the *Wiener klinische Wochenschrift* of February 1, 1900, is to be found a very exhaustive and profound article from the pen of Professor Schauta, entitled "Ueber die Einschränkung der Laparotomie zu Gunsten der vaginalen Cöliotomie," in which the author reports his experience, amounting to 1,112 vaginal cœliotomies and hysterectomies and 1,279 abdominal sections performed for various lesions of the uterus and adnexa, including the removal of one or both tubes for salpingitis, ectopic gestation, enucleation of fibroid growths, ovarian tumors, hysteropexy, etc. Death directly due to the operation shows for the vaginal method 2.8 per cent., and 5.9 per cent. for the abdominal. As to vaginal cœliotomy for lesions of the adnexa and uterus, when the condition of the latter organ did not necessitate its removal, we find 51 cases of single ovariotomy, 1 case of double ovari-

[1] Read before the New Hampshire State Medical Society, May 31, 1900.

otomy, 26 cases of removal of one tube for inflammatory lesions, 1 case of removal of both tubes for inflammatory lesions, 6 cases of removal of an ectopic gestation sac, 7 cases of enucleation of fibroid growths, and 178 cases of hysteropexy, making a total of 270 cases. Of these, three patients died, and all three were operated upon for inflammatory lesions of the adnexa. This makes a mortality of a trifle over one per cent.

In another recent and important paper on posterior colpocœliotomy for lesions of the adnexa and tumors of the small pelvis which was read before the Seventh Congress of Russian Physicians by Dr. P. Y. Teplor, the author mentions 184 cases, 51 of which are his own. Among these cases there were 48 operations for neoplasms and 136 for lesions of the adnexa. The neoplasms may be divided as follows: 34 cysts of the ovary (24 serous cysts, 7 dermoid cysts, 3 parovarian cysts), 10 proliferating cystomata, 2 cases of sarcoma of the ovary, 1 case of fibroid tumor of the broad ligament, and 1 case of cyst of the mesentery. In 13 cases the neoplasm was alone removed, while in 35 others removal of the adnexa was performed on account of inflammatory lesions present. None of the neoplasms was larger in size than a fœtal head. For the cases of inflammatory lesions of the adnexa, the following operations were performed: 23 cases of removal of the ovaries and tubes on both sides; 65 cases of removal of the adnexa on the one side; 3 cases of removal of both ovaries; 4 cases of removal of one ovary; 1 case of bilateral removal of the tubes; 18 cases of unilateral salpingectomy; 9 cases of bilateral extirpation of the tubes and removal of one ovary; 4 cases of bilateral removal of the tubes with partial excision of the ovaries; 9 cases of conservative incision of the posterior cul-de-sac.

In fourteen per cent. of these cases, suppurative lesions were present, and in 7 cases there was also present a retro-uterine hæmatocele. In 2 cases an ectopic gestation was found with the fœtus in a macerated condition. In 29 cases there was a retrodeviation of the uterus accompanying the lesion of the adnexa. Adhesions were met with in only two cases. The mortality was 3.8 per cent., and in 55 per cent. of the cases the post-operative convalescence was apyretic. In twenty-six per cent. of the cases there was no complication after the operation. In 4 cases an entero-vaginal fistula occurred, but which rapidly healed. In 42 cases certain complications were noted after the operation, such as a prolonged rise of temperature, bronchitis, pneumonia, parotiditis, urticaria, etc. The age of the patients varied between eighteen and sixty years; 15 were below the age of twenty years, 110 between the ages of twenty and thirty years, 51 between the ages of thirty and forty years, while 8 were between forty and sixty years. Among these patients there were 38 nulliparous females, or in other words about twenty per cent.

There have been a certain number of objections raised against colpocœliotomy by numerous surgeons. In the first place, it has been said that it was a slow operation. Now I admit that in a certain number of cases, and these form a small proportion, it takes some little time to draw the adnexa down and form a proper pedicle, but, generally speaking, the operation may be performed in from twenty to thirty minutes.

It has also been asserted that the clamps placed on the pedicle act as a very serious encumbrance, but in reply to this I would say that when the adhesions are not extensive the clamps should not be applied until a pedicle has been formed and the ovary and tubes are ready to be removed. In the vast majority of cases one pair of clamps is quite sufficient, and it will rarely be necessary to employ as many as three. If we are to remove the adnexa on both sides the clamps that have been placed on one side first may perhaps cause a little difficulty when being placed on the opposite side, but I have never yet operated on a case in which this could be counted as any hindrance to the performance of the operation.

The opponents of the vaginal route insist that it is a blind method. On this point I can say that in all cases which are suited to posterior colpotomy, the field of operation is as readily accessible to the sight as through an abdominal incision. You can always draw the adnexa down and examine them carefully before proceeding to their removal. The only part of the operation which is beyond the reach of the eye is when, before the pedicle has been formed, the finger breaks down adhesions and frees the adnexa. But with a finger well trained to abdominal surgery, we can feel the loops of the intestine and work with perfect ease and without danger. When the pedicle has been formed, the clamps are always applied under the entire and sole guidance of the eye. The use of an exaggerated Trendelenburg position is of great value in vaginal work, and even if we are dealing with a large cyst which bursts and empties its contents into the general peritoneal cavity, we run less risk by the vaginal route than by the abdomen, because we can get far more efficient drainage through the posterior cul-de-sac than from above.

The intestinal coils and the folds of the mesentery are so complex that even a most careful toilet of the peritoneal cavity may sometimes leave behind a drop or two of infectious fluid which will later result in sepsis, but the perfect drainage which is obtained through the vagina will in most instances prevent this from occurring. I purposely say, "in most instances," because I had the misfortune to lose a case last month from a most virulent streptococcic peritonitis, so virulent in fact that the patient died in thirty-six hours from the time of the operation. In this case the posterior cul-de-sac was opened and a large number of adhesions were broken down; the pelvic cavity was packed with iodoform gauze, but as there was considerable oozing from the vaginal incision the vagina was also tightly packed. On account of the vaginal packing drainage was imperfect, as is proven by the disastrous result which followed, but out of the fifty-nine cases of colpocœliotomies which I have now done for most varied affections of the uterus and adnexa, this is the only case that I have lost.

It has also been said that it is difficult to perform conservative surgery through the posterior vaginal incision, but here again I cannot agree. A partial resection of the ovary can be performed in many cases, and a hydrosalpinx may be opened and drained. Lawson Tait has said that an operation done through the vagina is always incomplete, but I would here point out that those instances in which a complete operation cannot be done through the vaginal incision are just the ones that should be operated on through the abdomen.

As to the argument that there is not sufficient space in which to work with ease, I would say that in my experience I have never yet met with a case in which the size of the vagina was any hindrance to the perfect result of the operation; but should this be found to exist, two lateral incisions in the perineum should be made, as is done in obstetrical practice to avoid laceration when the head is passing through. If we wish to ligate the pedicle instead of using clamps, it can be done with as much ease as through the abdominal incision, and as far as secondary hemorrhage is concerned it is no more likely to occur when the operation has been done through the vagina than when an abdominal incision has been resorted to.

Another objection which has been raised to the vaginal route is that antisepsis and asepsis cannot be

carried out to their fullest extent. Now as to this point I would say that the vagina can be rendered quite as sterile as the abdominal wall, and when the peritoneal cavity has been opened asepsis and antisepsis can be carried out just as well as through an abdominal incision. If we are dealing with an ovarian cyst which has undergone septic infection, and the purulent liquid escapes into the peritoneal cavity, it will remain in the pelvis and can be removed by sponges mounted on clamps just as well as through an abdominal incision, and here again the drainage being more perfect, on account of the natural inclined plane formed by the anatomical structures, the patient is placed in less danger than when this accident occurs during an operation through the suprapubic incision.

It has also been said that when we have once begun to operate through a vaginal incision it is difficult to stop if the condition of affairs is not found suited to this method. Now in the first place I believe that posterior colpotomy, and for that matter anterior colpotomy, is and always should be considered at the beginning as an exploratory operation. An organ should never be removed if it appears normal and if it has never given rise to any symptomatic phenomena. A purulent collection in the cul-de-sac of Douglas may be mistaken for a prolapsed cystic salpingitis, but when once the cul-de-sac has been opened the exploring finger readily discovers the error, and there is nothing simpler than to empty the pocket and drain.

As to the occurrence of a post-operative vaginal enterocele, I can simply say that I have never seen it occur in any of my patients, and all the cases I have operated on, both for pus in the pelvis or for the removal of the adnexa through the vagina, have always presented a few months after the operation an almost imperceptible firm cicatrix behind the cervix through which it would be impossible for any of the intestinal contents to form a hernia.

Post-operative intestinal occlusion, either acute or chronic, has never been reported after extirpation of the adnexa by the vaginal route, as far as I know. I believe that in comparison to the abdominal incision removal of the adnexa through the vagina is far less serious, that it results in a complete cure and avoids a suprapubic cicatrix, thus freeing the patient from any danger of ventral hernia.

There is still another advantage in colpocœliotomy. When one of these very persistent fistulæ arises which will occasionally occur after laparotomy, they are very difficult to heal and very annoying for the patient. Now in the case of the vaginal operation, if by chance a fistula does result, it is much more agreeable for the patient to have it in the vagina than in the abdominal wall.

When ligatures are not used on the pedicle, I of course resort to clamps, which are left in place from two to three days, and during this time the patient will complain of considerable pain, due probably to torsion of the broad ligament, but these pains can be easily controlled by the judicious use of morphine until the clamps are removed, when they will disappear as if by magic. The pain should never be considered a sufficient reason to condemn the use of the clamps, because in many cases the patients do not suffer any more than after an ordinary laparotomy in which ligatures have been used.

In those cases in which there is an inflammatory lesion of both adnexa the uterus is always considerably diseased, because it is the primary focus of the infectious process, the inflammation of the endometrium extending by direct continuity to the mucous membrane of the tubes. Now if we remove the adnexa in these cases, the uterus may be treated and its lesions cured, but if the parenchyma of the organ is thoroughly diseased, it should be removed along with the adnexa—in other words, a total vaginal hysterectomy should be done. On the other hand, the uterus may be perfectly normal, although there may be a lesion of the tubes, such as a hydrosalpinx, or an encysted hæmatosalpinx which has been produced by an unruptured tubal gestation which is undergoing absorption, and consequently in these cases the uterus should not be meddled with.

Anterior colpotomy is also useful in certain cases, such as the removal of fibroid tumors[1] situated in the anterior wall of the uterus, or for the performance of a cuneiform exsection on the anterior wall of the uterus for cases of retroflexion of the organ.[2] The incision is made transversely in the anterior cul-de-sac just as is done in vaginal hysterectomy, and then may be increased in size by carrying a longitudinal incision down perpendicularly to the first, and this latter incision should extend the whole length of the anterior vaginal wall just as is done in Mackenrodt's operation for retroflexion of the uterus, which will be described further on. The bladder is separated from the uterus as well as the vaginal mucous membrane for the extent of from 2½ to 3 cm. on each side of a longitudinal incision. The opening thus gained is quite sufficient for any radical or conservative operation we may wish to perform on the uterus or adnexa. I have never witnessed any disturbances of the bladder in the few operations I have done through the anterior cul-de-sac, and this is also the experience of Goffe, whose paper I have already referred to. In cases of simple retroversion of the uterus without adhesions, the uterus is easily reduced and may be brought into the vaginal incision, and then the adnexa may be examined. Next the round ligaments are shortened by folding them on themselves, and are held in this position by a few catgut sutures. In a simple case of this description the vaginal incision may be closed with catgut, and in a few weeks after the operation it is almost impossible by inspection to see that an operation has been performed.

In a certain number of cases the posterior incision may be combined with anterior colpotomy, which will very greatly facilitate matters. Very recently Stratz[3] has described an operation which he terms lateral colpotomy which I have so far performed on two occasions. It is very true that the lateral incision is the shortest through which to reach the parametrium, and in certain cases I believe that it is simpler, quite as easy, and less dangerous than anterior or posterior colpotomy. The great advantage that it has over the two latter operations is that the peritoneum is avoided, and as to wounding the uterine artery, or the ureter, the mishap is easy to avoid. To perform this operation properly, two long lateral retractors are placed, one in the anterior and one in the posterior cul-de-sac; the uterine artery is then recognized by its pulsation, and just behind it, and parallel to its course a transverse incision is made measuring from 5 to 8 cm. in length, commencing at the posterior and lateral aspect of the cervix. Through this incision the finger can easily attain the parametrium, decorticate it in its entire

[1] For further details see Dr. J. Riddle Goffe. "The Enucleation of Fibroids by Incision of the Anterior Vaginal Wall." MEDICAL RECORD, February 17, 1900, p. 304.

[2] Cuneiform resection of the uterus for retroflexion or anteflexion, devised by Jonnesco, of Bucharest, can be successfully performed through the vagina. If the flexion is anterior, posterior colpotomy should be done, while if we are dealing with a retroflexion anterior colpotomy must be selected. If the uterus is retroverted as well as retroflexed, cuneiform resection should be completed by a Mackenrodt's operation or by intra-abdominal shortening of the round ligaments.

[3] H. Stratz: "Kolpotomia lateralis." Centralblatt für Gynäk., No. 38, 1899.

height, and then the uterine artery, the ureter, and the lesions existing in the adnexa are easily recognized. By the use of long, narrow retractors to keep the operative wound well open, it is quite possible to work under the control of the eye, and the lesions may be separated from their adhesions and the whole brought down through the incision into the vagina. In most cases the peritoneum is out of danger because it escapes in front of the finger, and consequently it is not opened. Hemorrhage is here practically nothing, and the vaginal wound is so dilatable that Stratz affirms a fibroid measuring from 12 to 15 cm. in diameter can be removed through the opening.

It will be perhaps not out of place here to mention Mackenrodt's operation for retroversion of the uterus, because it has appeared to me that the technique has not been well understood by a number of surgeons. It is as follows: The cervix having been drawn down by two stout bullet forceps, a third one is then placed at about the middle of the anterior vaginal wall, which is then pulled upon so as to raise up and render tense the anterior cul-de-sac. It is then incised in its entire length from the point marked by the forceps in the anterior vaginal wall down to the cervix; at this point, a second incision is made transversely and thus two triangular flaps are formed that are dissected off and pushed back on each side. The bladder is then peeled back and held out of the way by a retractor, and a transverse incision is made in the peritoneal cul-de-sac.

Through this incision a pair of bullet forceps is introduced, guided by the index finger of the other hand, and the anterior wall of the uterus is seized at about 1½ or 2 cm. above the level of the internal orifice; a second pair of forceps seizes and pulls up the vesical flap of the peritoneal cul-de-sac. We now remove the bullet forceps which raises the cervix, and by the aid of the finger the latter is pushed backward, while with the bullet forceps placed on the corpus uteri the fundus is gently drawn forward and downward.

It should be understood that the finger which explores the pelvic excavation has already recognized and broken down, as much as possible, any adhesions which may bind down the adnexa. When the uterus has been brought forward, the forceps which holds the peritoneal flap which is adherent to the bladder pulls this flap against the anterior wall of the corpus uteri, exactly above the point where the forceps which brought the uterus forward has been placed. The flap is next sutured to the wall of the uterus by a single catgut suture. The peritoneal cul-de-sac is thus closed and at the same time is brought about 2 cm. higher than normal, and it thus results that below it is left bare about 1½ cm. of the anterior wall of the uterus, and it is on this very part that the bullet forceps which aided in bringing the uterus forward was placed. A large catgut suture is next passed into the parenchyma of the anterior wall of the uterus just underneath the last-mentioned pair of forceps, and the two ends are tied, and only at this point should the bullet forceps be removed and then be placed on the anterior lip of the cervix, which is again drawn down.

Next, the transverse incision of the vaginal cul-de-sac is closed by sutures beginning at the middle and going to the ends. There now only remains the longitudinal incision, whose upper angle allows the long catgut suture, which has been passed into the anterior wall of the uterus, to pass out through it. Each one of the ends of this suture is now threaded on a needle which is made to pass through a corresponding border of the longitudinal vaginal incision near its upper angle, sometimes also a little lower according to the length of the cervix. Before the two ends are tied, the vaginal incision should be carefully brought together by interrupted sutures, and it is only after this has been done that the uterus is held in position by tightly tying the catgut suture which goes through both anterior walls of the two organs. The operation is now finished, and all that is necessary is to pack some iodoform gauze in the vaginal cul-de-sac, which by pushing the cervix backward will hold the corpus uteri in its new position until cicatrization has become complete.

Vaginal fixation performed according to this technique usually gives satisfactory results. The pelvic organs retain their normal situation, and are in no way adherent to the pelvis or to the abdominal walls. The uterus is in good anteversion and perfectly normal; the corpus and fundus are absolutely free in the abdominal cavity, having their normal relations with the other viscera, and the bladder is only slightly pushed upward. The author of this method claims that the organ is so solidly held in place that neither labor nor pregnancy can in any way modify its position. Why I have described vaginal fixation of the uterus is, because in many instances along with the deviation of the organ will be found lesions of the adnexa which can be easily removed by the incision necessary for the correction of the position of the uterus. Generally speaking, however, the diseased tube or ovary has a tendency to prolapse into the posterior cul-de-sac, and consequently posterior colpocœliotomy will be the proper operation to select, because the adnexa are most readily reached in this way.

When a patient presents symptoms indicating the presence of some lesion of the adnexa which requires a radical operation, we should consider which is the better route for the given case, and in order to determine this point as correct a diagnosis as possible must be made. The difficulty is always to distinguish the predominating symptomatic elements, and to discover their pathogenesis so as to attack the cause directly. When once this has been determined, we may then resort to etiological therapeutics, which are the only ones that can have any pretension of being radical. In order to obtain this end, the personal and hereditary antecedents of the patient should be gone over, and all the viscera should be carefully examined. The genital organs should be the object of our special attention, and all the means of diagnosis which are used should be employed, such as digital examination of both rectum and vagina, bimanual palpation, percussion, and auscultation.

When it is necessary to distinguish a uterine or a peri-uterine tumor, a differential diagnosis with all those diseases which may possibly arise in the female pelvis should be considered, and a correct diagnosis will thus be arrived at, and this is absolutely necessary in order to avoid any error in diagnosis. If these precautions are not taken, an incarceration of a pregnant uterus may be mistaken for a fibroid, or a retroflexion may be diagnosed as some tumefaction located in the posterior cul-de-sac. In many instances, especially when the patient is very fleshy, it is absolutely necessary to employ general anæsthesia, and this should always be resorted to when any doubt exists as to the exact condition of affairs in the pelvis.

When the nature of the disease in the pelvis has been well established, as well as the necessity of doing something for its relief, we should consider whether or not the case is one for operation. If the patient is very weak, and unless the condition requires an urgent operation, the intervention should be delayed. During an attack of pelvic peritonitis, we should not try to remove an adherent organ; a prolapsed ovary, no matter how painful, should never be removed during pregnancy, but on the contrary, if we are dealing with a pregnancy complicated by a fibroid tumor of the uterus, the neoplasm should always be removed by either the abdominal or vaginal route, and

the choice of the operation will be settled by its position, size, etc. Generally speaking, every tumor which is larger than a good-sized apple, or which cannot be reduced to this dimension, should be removed by abdominal incision, but when it is below this size the vaginal route is the one which, in my opinion, is the best to select.

For the removal of the adnexa through the vaginal incision, they must be movable, or, if adherent, to only such an extent that they will not be prevented from being drawn down into the incision. If, on the contrary, they are immobilized by adhesions, and are situated high up beyond the reach of the finger introduced into the vagina, they would better be removed by abdominal section. When the adnexa are adherent to the uterus alone, the uterus itself must be movable so that it can be drawn well down in order to make them removable by posterior colpotomy. But when these conditions are not present, either anterior or lateral colpotomy is to be selected. In order to determine the exact condition of affairs in cases of adherent adnexa, examination under ether is usually necessary.

I would here like briefly to consider those cases in which removal of adnexa through the vagina is indicated. A painful, prolapsed, and sclerocystic ovary is one of the most frequent conditions, and is recognized by the very sharp pain produced by vaginal palpation; these ovaries may be so movable that they can be pushed around in the posterior cul-de-sac, and will slip away from the fingers like marbles. Another condition in which the posterior vaginal incision is indicated is in certain cases of suppurating or parenchymatous ovaritis. This also applies to small fibromas of the ovary which are characterized by their slow development, their usually small size, and non-malignant character. We can also open and drain cysts of the broad ligament, and partially extirpate them.

Diseases of the tubes may also be treated through the posterior vaginal incision, although their differential diagnosis is far from being easy in a large number of cases, and, in the absence of exact diagnosis, the gravity of the symptoms and the general condition of the patient should be our guide. There are many cases of catarrhal salpingitis in which pain is very severe, and which resist every kind of treatment employed, but in which an abdominal section is considered a pretty severe operation, in view of the slight importance of the lesion; posterior colpotomy may here be employed to advantage. Hydrosalpinx, hæmatosalpinx, and chronic hypertrophic parenchymatous salpingitis are easier to enucleate than a pyosalpinx. This latter lesion is so often accompanied by very tough and thick adhesions connecting the tube with the surrounding organs that in most instances the suprapubic route should be preferred. If, however, the tube forms a purulent pocket, it may be opened through a posterior vaginal incision and drained, a treatment which in many cases results in a complete recovery, usually a permanent one, especially when the lesion is unilateral.

To sum up the lesions which may be removed through the posterior vaginal incision, I would say that we have: (1) inflammatory affections of the adnexa with prolapsus in the cul-de-sac of Douglas; (2) cysts of the adnexa of small dimensions; (3) neoplasms situated high up in the pelvis, but which are movable and can be drawn down; (4) large cystic tumors, provided that they are not adherent and that by digital examination through the vagina the finger can easily reach the lower pole of the neoplasm; (5) solid neoplasms of the recto-uterine cul-de-sac which do not exceed the breadth of the posterior vaginal cul-de-sac; (6) extra-uterine pregnancy.

Vaginal salpingectomy is indicated in that condition known as encysted salpingitis. In this variety the adnexa, whether cystic or not, are contained in a secondary cyst which is formed of the remains of a former pelvic peritonitis. They are either bound down or are floating in a pocket which contains a serous, seropurulent, or purulent liquid, as the case may be. The upper wall of the secondary cyst has, as a characteristic, its being always made up of loops of intestine solidly agglutinated. The other walls are variable in structure. If the adnexa are in Douglas' pouch, the walls of this depression and the utero-sacral ligaments compose them. If they are in the retro-ovarian fossa, the anterior wall of the pocket is made up of the broad ligament, while the external and posterior walls become intermingled with the structures of the side of the pelvis, the internal wall having for substratum the utero-lumbar and the utero-sacral ligaments. The cyst formation may also take place in front of the broad ligament in the paravesical fossa; but no matter what variety of cystic formation of this type we may be dealing with, its vault is always the same, that is, composed of an agglomeration of agglutinated coils of intestine.

Encysted salpingitis is usually better dealt with by posterior colpotomy than by any other method, and most of it can be removed through the incision, and what is left will be eliminated by drainage.

I believe that retro-uterine hæmatocele can be best treated by the vaginal route, provided that all symptoms of hemorrhage have ceased, and that the collection of blood has become encysted, but I will not insist further on this point, as it has been discussed in my paper already alluded to. The treatment of tuberculous peritonitis by posterior colpotomy as recommended by Löhlein does not appear to me to present the advantages possessed by abdominal section.

Generally speaking, posterior colpotomy is contraindicated in those cases which do not present any of the conditions already mentioned, and the knowledge of the indication will be sufficient to determine whether the vaginal route is the proper one to select or not. The contraindication may be due to the general condition or the local condition. An extreme debility, an acute disease, or pregnancy would naturally lead us to defer the operation excepting when the case is one of emergency.

The contraindications given by the local condition are far more numerous and important. To operate for the removal of an ovary during an acute attack of pelvic peritonitis would naturally be a very serious mistake, excepting in those cases in which the inflammation of the tube is due to direct infection from an adherent appendix which is acutely inflamed, but in these cases the usual incision for appendicitis on the right side of the abdomen is the proper one to select. If a cystic purulent salpingitis which is adherent to the wall of the vagina, and filling out the cul-de-sac, is present, it is not the removal of this condition that should be undertaken, but a simple incision followed by drainage is all that is necessary, and to attempt anything else would be both difficult and dangerous. In other cases in which the lesions of the adnexa are extensive and situated on both sides, the adhesions set up by a chronic pelvic peritonitis are very numerous. There are in this case a perimetro-salpingitis and a cellulitis, and consequently we should remove everything which binds up these collections; in other words, a total vaginal hysterectomy should be done. Excepting in the case of encysted salpingitis, abdominal incision should be preferred on account of the intestinal adhesions, because when we try to break them down the intestine may be torn, and this mishap is very difficult, if not to say impossible, to repair through the vaginal incision.

It is very true that a diagnosis of the presence of intestinal adhesions is difficult to make, but there are certain signs which will at least lead us to sus-

pect their presence. Disturbances in defecation and digestion, intestinal dyspepsia, colics, chronic intestinal occlusion, or the presence of gas felt when a certain point of the tumor is palpated, are all symptomatic of intestinal adhesions, but in spite of all these symptoms they are oftentimes not suspected. Consequently if, after having opened the posterior cul-de-sac, this condition of affairs is found, the surgeon should proceed with caution, and if he is well trained in abdominal surgery his finger will readily ascertain how far the operation may be carried. If the tumor is tightly bound down, and abdominal incision cannot accomplish more than the vaginal route, the posterior cul-de-sac should be opened and the tumor incised and drained.

To sum up, it may be said that extensive adhesions are a contraindication to the removal of these pathological conditions even by the abdominal route, but unfortunately in many instances we are not aware of the condition until the parts are explored by the finger. A very high position of the adnexa in the pelvis, and more especially the impossibility of bringing them down low enough to be within reach, are absolute contraindications for posterior colpotomy, and the abdominal route should then be selected. A high position of the uterus, in which it cannot be drawn down without difficulty, enters into the same class. If the adnexa are adherent in the paravesical fossa, anterior colpotomy is the operation to select; and the last contraindication to which I would call attention is a malformation of or a very tight vagina.

The technique of the operation I have discussed very fully in the paper already alluded to, so I will not refer to it here. Suffice it to say that the patient is placed in the lithotomy position with the thighs well flexed on the abdominal wall. I always use an exaggerated Trendelenburg's position in these cases, and for this purpose there is no table equal to that devised by Pryor of New York. The use of ligatures or of clamps will depend entirely upon the preference of the operator, but personally I prefer the latter in many cases. I have never seen any advantage in closing the vaginal incision with sutures after the removal of non-suppurating lesions, and rather prefer to insert a wick of gauze which is removed in three or four days, and within a week or ten days from the time of the operation the incision will be found to have completely closed.

871 Beacon Street.

HÆMATOMYELIA, WITH REPORT OF THREE CASES.[1]

By W. F. BECKER, M.D.,

Milwaukee, Wis.,

Consulting Neurologist, Milwaukee County Hospital.

Spinal hemorrhage, even excluding that incidental to vertebral traumatism, is, perhaps, not so uncommon as is generally supposed, the opinion expressed only about twenty-five years ago being that it did not exist in its primary non-traumatic form. Mild cases improve and do not come to autopsy, others no doubt are masked under the diagnosis of spinal meningitis or myelitis. Compared, however, to cerebral hemorrhage, it is of course quite rare. This is owing, no doubt, to the longer and more tortuous course of the spinal blood-vessels, their smaller size, and the less frequent changes in the blood pressure therein. Thus we find no miliary aneurisms in the cord, which in the brain are the forerunners of hemorrhage.

The text-book distinction of hæmatomyelia or hæmatorrhachis, according as the bleeding is in the cord or membranes, seems to be more anatomical than clinical. Though it has some theoretical justification in the blood supply, it is certainly not entitled to the same weight as the same distinction in cranial hemorrhage. While the existence of pain points to the membranous form it is not a reliable discriminator, as will be seen in one of the cases here reported. Bleeding in the cord is more apt to take place in the gray matter, where the vessels are more numerous, have less support, and are probably subjected to more changes in lumen than in the white matter.

The causes of spinal hemorrhage of the primary kind, with which only we are here concerned, are obscure. Anæmia in its protean forms has been associated with many cases; so also severe exertion of the muscles of the back, as in a case that took place during excessive coitus, and in one here reported in which the patient was engaged in the prolonged use of the sewing-machine at the time. In both of these the lesion was in the portion of the cord innervating the muscles engaged (lumbar enlargement), which may have some bearing on the matter. Such possible bearing is not to be identified with the instances in which general convulsive seizures produce the commonly found punctate hemorrhages. These are more properly classified as traumatic, and are often in proportion to the violence of the spasm.

The symptoms of spinal hemorrhage are attributable to varying degrees of interference with the motor, sensory, trophic, and reflex functions of the particular spinal segments affected. Each segment of the cord, it will be recalled, is not only engaged in conducting motor and sensory impressions to and from parts below it, but by virtue of its gray matter and anterior and posterior nerve roots innervates a given muscular area, presides over its nutrition, and receives sensory impressions of a given cutaneous area, and looks after the trophic, reflex, and vasomotor functions of the same. Each of these segments contains groups of cells which preside over certain "movements" rather than muscles, thus differing from the distribution of peripheral nerves, which often supply adjacent muscles which may have opposite actions. These groups of cells, which often overlap, rarely occupy only a single segment, and usually extend through several, so that certain muscles, probably according to their various actions, and also to their size, receive their innervation from a varying number of segments. Thus the biceps, which is a supinator as well as a flexor, indeed first a supinator, as one may easily prove by faradizing it, has three segments. The supinator longus, which is a flexor as well as a supinator, and perhaps more of a flexor, has its group of innervating cells extending through two.

I shall not speak of spinal localization except to say that I have found it useful to picture the body in the quadruped position, when it will be found that there is a fairly regular correspondence between the segments and the muscles supplied by them from before backward. Thus the deltoid and biceps are supplied before the teres major and triceps, which are more posterior in this position; the radial side of the arm sooner than the ulnar side; the psoas-iliacus sooner, *i.e.*, from a higher segment, than the quadriceps extensor, and this in turn, lying more anterior than the hamstrings, is supplied by a higher segment. The perineal muscles being most caudal in this position are supplied by the lowest segments. The same general sequence will be found to prevail even more perfectly in regard to the sensory distribution. Thus a lesion in the lowest segment produces anæsthesia at the very caudal extremity; a little higher and the posterior part of the thighs and legs are affected, and so on. I have also found it convenient for localization to single out only the chief muscles, those whose con-

[1] Read before the Milwaukee Medical Society, December 12, 1899.

dition is easily determined as affected either by paralysis or atrophy, or in response to electrical stimulation, and to make a diagram on such a basis. Such a treatment, however, of a complicated subject, which is largely yet a *terra incognita*, may be regarded as only roughly convenient, and must not be used to the sacrifice of accuracy or to a more detailed study in particular cases.

In determining the exact point corresponding to the affected segment I may be excused for recalling two important things: First, that a given segment lies higher than its corresponding vertebra. This relatively higher position of the segment to its vertebra increases as we go down the cord, and so the nerves as they emerge from each segment to reach the intervertebral foramina of the corresponding vertebra have an increasingly longer intra-medullary course as we go down, and, the cord ending at the first lumbar, all nerves destined for intravertebral foramina below this (lumbar, sacral, and coccygeal) must leave the cord at this point. Secondly, we must remember that the spinous processes of the vertebra, which are our only guide to their localization, do not always lie opposite their bodies. This is distinctly true in the dorsal region, where from about the second to the eleventh the spinous processes project markedly downward so as to lie over the body of the vertebra next below and even lower. To illustrate these points, a horizontal line passing in from the seventh dorsal spine would pass through the lower part of the eighth dorsal body and go through the ninth dorsal segment. Or, putting it contrariwise, the ninth dorsal segment lies opposite the body of the eighth dorsal vertebra, which lies opposite the spinous process of the seventh.

In regard to localization in the cervical region it should be remembered that the first vertebra has no spinous process, that the spinous process of the second is very large and distinct, and that in the third, fourth, and fifth the spines are sometimes absent and are generally bifurcated, which makes it difficult to distinguish them; the sixth is also inconspicuous, and the vertebra prominens, instead of being the seventh cervical, is generally the first dorsal.

The least equivocal picture of spinal hemorrhage is the sudden onset of paralysis and anæsthesia without loss of consciousness, the paralysis reaching its maximum intensity in a short time, then receding early to a greater or less extent *pari passu* with relief of pressure by shrinkage of clot or subsidence of shock (the continuance of improvement depending, of course, upon the destructive or compressive nature of the lesion); the presence of pain or other sensation in the back; the disturbance of the bladder and rectum; the flaccid nature of the paralysis of the muscles innervated by the affected segments, with a loss of their deep reflex activity and a quantitative change to faradism and galvanism, and later qualitative changes to galvanism with R. D. and atrophy; and the spastic nature of the muscles below the affected segment, owing to injury of the conduction paths, with an increase of their deep reflexes and absence of electric changes; the girdle sensation with an area of hyperæsthesia at about the level of the affected segment; the absence of the superficial reflex of the segment involved, though its presence is a better sign of the integrity of the segment than its absence is an indication of the involvement thereof.

While such might be a clinical picture of a transverse lesion produced by a large hemorrhage, a smaller hemorrhage, by virtue of its predilection for the gray matter, is apt to produce a symptom complex which has come to have almost pathognomonic significance, namely, a dissociated anæsthesia, *i.e.*, a loss of temperature and pain sense with a retention of the tactile sense. Through the study of syringomyelia and other means, we have come to locate the conduction paths of pain and temperature in the gray columns, while the tactile-sense paths are in the posterior white columns. A smaller lesion, therefore, is thus apt to affect only the pain and temperature sense of the gray matter, leaving undisturbed the tactile sense, and this has been observed to be so clinically corroborated in a number of cases as to make it a very characteristic symptom of hæmatomyelia.

As in other nervous diseases, however, aberrant forms are perhaps more common than the typical. Much in diagnosis depends upon the reliability of the symptoms gathered, the returns of examinations often being ambiguous. It is usually more difficult to gather exact data, making due allowance for subnormal variations, than to interpret the same. Young and lean persons furnish the least equivocal data, the young because of the greater reliability of the sensory and reflex functions, the lean because of the easier reading of the musculature.

Antecedent cord disease in which hemorrhage may be incidental should always be suspected in a case supposed from its sudden onset to be spinal hemorrhage. Even post mortem it may be difficult to know whether a hemorrhage was primary to the softening of contiguous myelin or secondary to a myelitis. On the other hand various paræsthesiæ, which may be brief forerunners of hemorrhage, must not be construed as indicating antecedent cord disease. Gliomata, too, may bleed in the cord, as they commonly do in the brain. Their softness and imperfect differentiation from adjacent nerve tissue make it possible for them to exist without decided symptoms, though for mechanical reasons this is less true in the cord than the brain, where I have found extensive gliomatosis of the right hemisphere without any brain symptoms whatever. Pott's disease, also, may pre-exist (though not so likely to be unsuspected), and symptoms caused by the pressure of broken-down tissue may come on suddenly enough to simulate hemorrhage.

Spinal hemorrhage is not so easily confusable with cerebral hemorrhage, though they have in common the sudden onset of paralysis. Those cases, however, in which the apoplectic insult in the cord is accompanied by reeling or faintness due to shock, may easily be mistaken for that form of cerebral hemorrhage in which, because of the position or severity of the lesion, consciousness is but little disturbed, especially were the paralysis more hemi- or monoplegic than paraplegic.

More confusable, perhaps, are cases of multiple neuritis, in which atrophy and electrical changes may be the same, as well as motor and sensory disturbance and a fairly sudden onset. The absence of bladder and rectal disturbance, the very characteristic pain along affected nerves and muscles, the probably irregular distribution of the paralysis and anæsthesia, particularly the latter, the pseudo-tabetic symptoms arising from the disturbances of muscular sense, associated with pain, and the absence of girdle sensation and myostatic irritability of muscles below the lesion, and the absence of dissociated anæsthesia, favor neuritis as against hemorrhage.

Hysterical or functional paralysis of the spinal type will often come to mind in explanation of the symptoms produced by spinal hemorrhage. Each may come on in anæmia, and with considerable suddenness affect motion and sensation with flaccid or spastic type of paralysis. In discriminating between them the absence of hysterical stigmata, psychic or nervous, must not carry too much negative weight; at the same time it is an easy snare when symptoms are bizarre and coupled with a few stigmata to lay them to hysterical or functional causes and give a good prognosis. While globus, tremor, spasm, deep hemianalgesia,

sentimentality, suggestibility, and want of inhibition have due weight, we are more and more learning, as Seguin pointed out years ago, that organic disease and hysteria often coexist, the gross lesion provoking latent hysteroid symptoms in a potential hysteric. In discriminating, the irregular, bizarre nature of the symptoms which cannot easily be explained by a focal lesion; the fact that the paralysis often affects "combined" movements rather than individual muscles, producing a disability of walking rather than of moving the leg muscles, or of writing rather than paralysis of individual arm muscles; the fact that a mental strain, notably worry and fatigue, has preceded; that convulsive seizures of a general character and not confined to the muscles to be presently paralyzed, as in organic lesions, have occurred; that the special senses are affected; that there may be decided fluctuations in the symptom complex—all of these must favor hysteria. Many, however, may be absent, and the diagnosis not be so easy, for even atrophy of muscles, bedsores (small) and bladder disturbances are not necessarily absent in either hysterical or functional paralysis, and the generally described sudden disappearance of hysterical paralysis is the exception rather than the rule, according to men of large experience, Mitchell, Bastian, and Charcot.

Case I.—My first case is that of a married woman aged thirty years, anæmic and "run down," who, while sewing for a protracted time at her machine, started to walk across the room, when she felt faint and sank to the floor. Unable to rise, though still able to move her legs slightly, she was lifted to a couch, when the paralysis soon become complete. Hot water was then applied to her legs, which, being thermo-anæsthetic, were thereby severely scalded. When I saw the patient a fortnight later there was complete paraplegia; the muscles were flaccid, the knee jerks absent; bladder and rectum were affected, the voluntary sphincteric control being lost so that they emptied themselves without central authority. Tactile sense was but slightly diminished over the lower extremities including the lower abdominal region, but pain and temperature sense were abolished over the same parts. The epigastric, abdominal, and plantar reflexes were intact. The deplorable state of the patient was magnified by the fact that she was now in the fifth month of pregnancy.

After about two weeks from the onset it was noticed that some motion had returned to the right foot, the patient being able to flex the toes slightly. This was not accompanied with any improvement in sensation, or, if so, it was so slight as to be unreliable. The bladder and rectum continued incontinent, and notwithstanding catheterization the residual urine soon developed cystitis. In spite, also, of attention to the trophic condition of the skin a small bedsore soon appeared on the foot, and the injury sustained by the scalding of the legs did not heal. No particular atrophy of the muscles developed.

Symptoms pointing to the death of the fœtus led to the induction of labor, though the child was found viable. No anæsthetic was required for the forcible dilatation of the os, which was entirely painless, nor was there any pain in expulsion of the fœtus, the uterine contractions, however, being firm and potent, and no bad after-effects followed the operation.

The patient soon become worse; bedsores developed which could not be checked, and one of great size over the sacrum produced general infection which rendered cutting away of the slough necessary, and languishing in this way she died, after having lived about six weeks without once having her mind obscured to her condition.

The position of the spinal hemorrhage as it was inferred to be, no autopsy having been granted, was in the lumbar enlargement somewhere between the abdominal reflex arc above (eleventh and twelfth dorsal) and the plantar reflex arc below (first sacral), both of which were intact. The involvement of the knee-jerk centre (third lumbar) and the flaccid nature of all the paralyzed muscles place the lesion in the lumbar segments and probably greatest in the upper ones. The improvement in the foot and the escape of the direct bladder and rectal reflex arc (those organs suffering only from an interference with voluntary control from above and not from a breach in their reflex centre, in which case there would have been paralysis of the detrusor with retention, or of the sphincter with constant incontinence), show the escape of the sacral segments. Though the lesion was probably large it does not require so very extensive a lesion to affect all the lumbar segments, as these segments lie quite closely superimposed here. That the lesion was chiefly in the gray matter is apparent by the flaccid nature of the paralysis. If the white conduction paths were involved, and they are comparatively few here (the sensory ones having not yet been gathered in for their brainward course, and those destined for muscles having been largely distributed above this point), the spasticity accompanying such involvement of the lateral tracts may have been counteracted by the greater and more vertically extensive anterior cornual lesion. That there was no marked atrophy under these circumstances seems anomalous, (the greater adipose of a woman's legs, however, easily conceals lesser degrees of muscular atrophy). Though the separate existence of motor and trophic cells in the gray matter is probable, it is not likely that the latter would escape in such an extensive lesion as this, which practically destroyed the independent function of the cord in several segments as well as its conductive function, allowing nothing but a small degree of tactile sense to penetrate upward. That the lesion was destructive rather than compressive is shown by the little or no improvement. All of these inferences must, however, go unverified by post-mortem diagnosis.

The behavior of the uterus is of interest in this case. The strong contractions seem anomalous, especially in the absence of sensation necessary to awaken the reflex function. This anæsthesia, however, was probably only that of the pain sense, which, transmitted through the cord by way of the sacral segments, was interrupted by the lesion, while the tactile or other sensation in the uterus necessary to excite the reflex arc through the hypogastric plexus was uninterrupted and requisite to engage the uterine mechanism, the probable centre for which Onuf has recently shown to be in the so-called vegetative cell column of the third sacral segment, which was here inviolate.

As possible causative agents it may be mentioned that the woman had taken many doses of an unknown oxytocic to effect abortion; also the fact that there was more or less anæmia (though no blood count was made), and the fact of the prolonged innervation of the lumbar segments in the protracted use of the sewing-machine. There was no nephritic or alcoholic history, though a syphilitic one could not be entirely excluded.

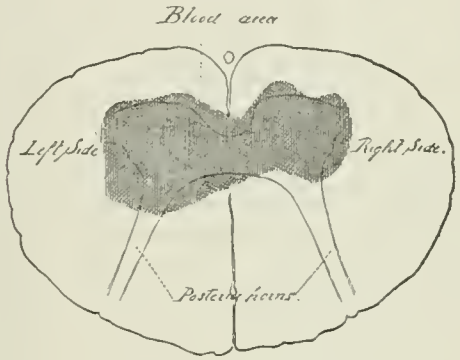
Case II.—Mr. P——, aged thirty-eight years, with alcoholic and syphilitic history; the patient is addicted to absinthe. Coming home one night, not intoxicated, he reeled and partly fell down a step or two leading to the basement of his house. He was helped to a chair and found himself unable to move the left arm or leg. Soon he dropped from the chair to the floor, and then his right side was found immovable as well. There was no disturbance of consciousness, no deviation of head or eyes. When I saw him a few hours later there was complete paraplegia from the shoulders down; no facial or ocular paralysis. The

tongue deviated to the right (which was probably, however, a normal deviation); his mind was clear; there was severe pain over the post-cervical region, where there was no sign of trauma, but where pressure elicited tenderness: the arm paralysis was flaccid; the legs were spastic, the knee jerks being exaggerated, though no ankle clonus was present. There was little or no disturbance of sensation or superficial reflexes. There was vomiting, probably due to medicine. There was apnœa which gradually increased. Later, loss of voluntary bladder control was manifest; the respiratory difficulty increased, and the patient died about thirty-eight hours after the onset, with mind clear almost beyond the threshold of death. An autopsy was reluctantly granted, and only the upper portion of the cord was removed. Exudate, probably post-mortem, was found around the cord, the precaution not having been taken to lay the body prone as is desirable when the cord is to be examined. On section of the removed cord there was found a red hemorrhagic area which might in its fluid state have been about two teaspoonfuls of blood. It occupied the middle of the fourth cervical segment and extended to about the middle of the sixth. The clot was found to be in the gray matter and chiefly of the ventral horns, and greatest on the left side, corresponding to the initial paralysis. The clot was largest at the fifth segment and on the left side, which was probably nearest to the bleeding vessel, which vessel could not be found. It encroached upon the lateral tracts chiefly by pressure. The membranes were unaffected, which fact leaves the pain unaccounted for (see figure).

Coming on suddenly in the form of hemiplegia the symptoms at the outset in this case might have been regarded as cerebral, especially with the deviation of the tongue to the right and the vomiting. The early supervention of the paralysis on the other side, however, and the absence of involvement of speech, face, or consciousness, would have cleared away any doubt, especially the apnœa, indicating paralysis of the phrenic nerve. Though the situation of the clot was mostly below the chief innervation of that nerve, the largest mass of it was in the fifth segment, which sends a communicating branch to the phrenic. Death from apnœa might have come sooner had it not been for this escape of a large part of the phrenic innervation. Though it has been established that paralysis of the diaphragm alone without involvement of the auxiliary muscles of respiration, such as the intercostals and scaleni, is not fatal, the lesion in this case was low enough to enable the scaleni and sterno-mastoid to be in active play as auxiliaries. From some recent experiments on the faradization of the phrenic nerve in the neck to maintain artificial respiration, it is not too much to claim that in lesions like this in which the clot just edged upon the phrenic-nerve origin, such faradism of the diaphragm might be a useful therapeutic measure, pending whatever restitution of diaphragmatic function there may have been through shrinking of the clot or subsidence of the shock. The respiratory difficulty in this case was very characteristic. It could not be mistaken for dyspnœa, either inspiratory or expiratory, for there was no air with which to breathe; the patient would open his mouth, and jerk his head forward as if to bite off pieces of the atmosphere which refused to enter where the paralyzed diaphragm made no vacuum.

The lesion involving the innervation of the brachial plexus directly through the gray matter, and the muscles below indirectly by pressure on the lateral columns, explains the flaccid nature of the paralysis of the arms with diminished myotatic irritability (and also changed electrical reactions with atrophy had there been time to develop these), and the spastic paralysis of the legs with increased knee jerk. That sensation should remain unaffected in this case makes the lesion and symptom group a curious parallel to that chronic spinal disease, amyotrophic lateral sclerosis, in which there is a paralysis of the upper extremity of the peripheral neuron type, with atrophy, R. D., fibrillation, and of the lower extremity due to affection of the central neuron, with increased myotatic irritability.

Case III.—This is a case of a young married woman who has had one child and had always enjoyed fair health, having no syphilitic, alcoholic, or neuropathic history. About one year ago without warning she had pain in her back, and dragged herself to a couch, where in less than an hour her legs, as she said, "went to sleep," and became completely immovable. Soon after that she had no restraining influence over the bladder. The paralysis seemed to reach its height at once and straightway began to improve, some motion of the legs being possible on the following day. I saw the patient for the first time nearly four months after, when she was just beginning to trust herself to step. At that time her movement was stiff; the mus-



cles of both legs were weak, and the knee jerks were much increased, which increase was more marked on the right side, where there was also slight ankle clonus (about eight contractions); there was also some atrophy of the right leg, which measured three-quarters of an inch less than the left. About the same relative difference existed in the thighs. As there was little adipose tissue, and the legs were normally small, even such a slight degree of atrophy was important, particularly on the right side. Electrical reaction showed quantitative changes in faradism and galvanism on the right side, but no R. D. Slight tactile anæsthesia existed, greater on the right side and increasing toward the extremities. Pain sense was also affected in the same manner, but there was no thermo-anæsthesia. Both extremities were subjectively and objectively cold, the right more than the left. The superficial reflexes were not abnormal. These symptoms were probably due to hemorrhage of the cord, small in extent, and greatest upon the right side, and having little or no destructive character, as subsequent improvement showed. It is a little difficult to understand how a lesion could press upon both lateral columns without doing more damage to the intervening gray matter. Two ways are open to explain this: one is the morphological anomaly by which there is little pyramidal decussation, the tracts of both sides lying contiguous in the anterior columns (Türck's), where a lesion might easily affect them both as well as damage the right anterior horn; or, what is more probable, that originally the gray matter had been damaged transversely to the extent of affecting the lateral tracts, which damage, however, had been largely remedied four months after, when my examination was made. For want of early observation the precise position of the lesion is not determinable, though probably in the upper lumbar segments. No other theory of diagnosis is as tenable as hemorrhage. An adult form of acute anterior cornual myelitis, though

having the fairly sudden onset and the characteristic coldness of the limb, is negatived by the presence of the knee jerk, the bladder disturbance (which is very rare in poliomyelitis), and the presence of sensory disturbance, however slight. Hysterical or functional paralysis might be read into some features of the case, but the patient is a sensible, cheerful, happily married and favorably situated woman, and worry and fatigue are wanting. Neither could it be the common paraplegia of alcoholic, syphilitic, or metallic poisoning, which, excepting the syphilitic, are peripheral in their nature, although we are more and more losing the sharp distinction that has always been made between peripheral and anterior-horn lesions. That there is no progressive system disease of the cord is shown by the fact that no symptoms antedated the onset and that there has been progressive improvement since. This has continued, at first rapidly, later more slowly, under faradism, massage, strychnine, etc. She soon became able to walk about the street without support, later to go up and down stairs, although the feeling of stiffness remained; the legs and thighs improved in nutrition and warmth, until examination a few days ago showed no atrophy, the legs and thighs measuring the same. The right knee jerk was no longer greater than the left, though they were both still exaggerated. Tactile and pain sensations, which had been in arrears in former examinations, were, if diminished at all, very slightly so. The bladder irritability had disappeared within a few weeks, but the rectal trouble, in the nature of diminished expulsive power, from which she had suffered since the beginning, continued. Believing that this had no relation to the lesion, but was due to the sedentary life which she was obliged to live, and the constant resort to cathartics necessary, the patient was recently advised to discontinue their use and allow the rectum to regain its reflex activity even at the cost of much constipation. Under this the patient would at first go for more than a week without bowel movement, during which she suffered headache and other discomfort, but on persevering the normal evacuations came oftener, until now they take place about every two days. The subjective sense of slight stiffness continues, and also a slight spasticity in her gait, which is not noticeable unless looked for, and with the exception that she cannot indulge a fondness for dancing, or hurry after a street car, she is almost as well as before her trouble a year ago.

If the lingering stiffness is the result of some degeneration in the so-called inhibitory fibres of the motor tract from some destruction therein, we have, on the one hand, the unfavorable precedent in which the section of monkeys' cords was followed by little or no restoration of function, and, on the other hand, the favorable precedent in the great improvement of the spasticity in Pott's disease when regular mechanical treatment is applied, as conflicting features as to the ultimate integrity of the patient's cord. That there has already been considerable improvement in this is a fair ground for expecting more.

Facial Paralysis in the Course of Acute Catarrh of the Middle Ear.—L. Bar reports three cases: In the first, that of a girl aged nine years, an otitis following influenza was accompanied by a paretic state of the facial muscles; puncture of the drum quickly relieved all untoward symptoms. The second case was in a boy aged eight years, with adenoids, and presented similar symptoms, with the same happy result following puncture: the power of the facial muscles in both was restored inside of twenty-four hours. The third case, occurring in a woman, was of longer duration, and involved the muscles of the tongue as well as those of the face. Later history showed the involvement of the mastoid. Opening of the latter was followed in the course of a week by gradual improvement, which was complete so far as muscular power was concerned five days later. —*Revue Hebdomadaire de Laryngologie, etc.*, June 16, 1900.

Affections of the Eye Associated with Lesions in the Kidney.—W. O. Moore describes albuminuric retinitis, amaurosis uræmica, and alludes to paralysis of the ocular muscles, stating that the abducens is the muscle most frequently affected. The retinitis is at times unilateral. The pathological change in the retina is not, according to Moore, an inflammatory one, but is a tissue metamorphosis which produces permanent changes in the retina and is brought about by the changes in the vascular system generally, which in turn are caused by the circulation in the blood of effete material due to imperfect elimination by the kidneys. This material may be urea alone or in combination with other substances. The prognostic significance of this retinal change is bad, death following as a rule inside of two years.—*The Post-Graduate*, July, 1900.

The Use of Opium in the Summer Diarrhœas of Children.—F. M. Crandall says that opium, under the conditions specified, is contraindicated (1) in the first stages of acute diarrhœa, before the intestinal canal has been freed from decomposing matter; (2) when the passages are infrequent or of bad odor; (3) when there is a high temperature or cerebral symptoms are present; (4) when its use is followed by elevation of temperature or the passages become more offensive. It is indicated (1) when the passages are very frequent, with pain; (2) when the passages are excessively frequent, large, and watery; (3) in dysenteric diarrhœa preceded by castor oil or a saline; (4) in late stages, with small, frequent, nagging passages; (5) when the passages consist largely of undigested food, and the bowels act as soon as food is taken into the stomach.—*International Medical Magazine*, July, 1900.

The Etiology of Congenital Dislocation of the Hip.—Bode, in studying the causative agencies at work in producing this deformity, groups them under three heads: (1) Those involving the fœtus alone; (2) those emanating from conditions in the environment of the fœtus; (3) those resulting from a combination of these two. In conducting a series of investigations on this subject by means of the Roentgen rays he found that only the first set of these factors was susceptible of study in this way; skiagraphs of the fœtus in utero are still too imperfect to be of any assistance. Accordingly, the hip joints of one hundred and fifty children (including fifty-six fœtuses) were radiographed, two hundred and six of these being diseased and ninety-four normal. Owing to the comparatively late date at which the acetabulum and the head and neck of the femur ossify, the plates prepared from the fœtuses do not show anything of value, but careful pelvic measurements were made. In twenty-five per cent. of the children suffering from unilateral congenital dislocation the supposedly normal side was found to exhibit the typical lesions to a slight degree. In general, the change found consisted in an increased breadth of the acetabular cavity, in flattening of its upper margin, in lateral thickening of its wall, or in asymmetrical atrophy and altered growth tendencies of the femoral head. The conclusion is that congenital dislocation is the direct result of morbid processes of unknown etiology and dating from the earliest periods; if these pathological changes are slight, no deformity results; if they are well-marked, a dislocation takes place.—*Centralblatt für Chirurgie*, July 14, 1900.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, August 18, 1900.

THE SIGNIFICANCE OF DEGENERATION OF RED BLOOD CORPUSCLES.

IMPORTANT additions have been made in the past decade to our knowledge especially of the morphology of the blood, but we are without an explanation fo many of the phenomena observed. It is, besides, difficult to state whether some of the peculiarities are the result of regenerative or of degenerative processes, and a ready means by which a correct decision could be reached would be a useful addition to our clinical resources. Valuable therapeutic suggestions might, further, be obtained from a knowledge whether the essential disturbances occur in the plasma, in the red cells, or in the white cells—apart from the prophylactic significance a more thorough etiological knowledge would possess. In a recent communication Grawitz (*Berliner klinische Wochenschrift*, 1900, No. 9) discusses at length the pathological significance of certain basophilous granulations that he has found under certain circumstances in red blood corpuscles, even in the absence of other signs of anæmia in the blood, and that he considers with certainty as indicative of a degenerative process. When present, these can be demonstrated in dry preparations by staining with methylene blue after fixation with alcohol. Granular red blood corpuscles have been noted in cases of pernicious anæmia by several observers, who have considered them as the remains of dissolved nuclei. Grawitz, however, has found such corpuscles in the total absence of nucleated red corpuscles, and also red corpuscles with intact nuclei but containing likewise many granulations. Unlike the nuclei themselves the granular matter, further, cannot be stained with methylene green. Granular red corpuscles are not found in the bone-marrow in any greater number than in the general circulation, as they would be if they were indicative of karyolysis. In aggravated cases of pernicious anæmia erythrobiasts with fibrillated nuclei and constricted portions of the nuclei may rarely be found, but the appearances of these are unlike those of the granular degeneration under consideration.

The granular red cells are particularly numerous in cases of pernicious anæmia. They are found frequently also in cases of carcinoma, and especially when the new growth is so situated as to favor absorption of toxic products, as in the digestive tract. They have likewise been observed in cases of advanced leukæmia and in association with septic processes. The granules are remarkably numerous in the blood in cases of lead-poisoning. This is all the more noteworthy because, in spite of the pallor present, morphological alterations in the blood are usually absent in cases of this kind. The absence of these peculiar granules is considered not less significant than their presence, tending to exclude the action of a blood poison. The granules have not been found in cases of chlorosis, and this evidence seems to confirm the view that the disease is not of toxic origin, but due perhaps to vasomotor disturbances. The granules are not found in cases of pulmonary tuberculosis free from excavation and hectic fever, nor in cases of syphilis, chronic parenchymatous and interstitial nephritis, and cirrhosis of the liver. These granules are looked upon as evidence of a degenerative process due to the action of blood poisons. It is possible to cause their appearance in mice by exposure to a temperature of between 98.6° and 104° F., and the presence of iron granules in greater amount in the liver is accepted as an indication of increased destruction of hæmoglobin. In this connection it is suggested that some forms of tropical anæmia may have a like mechanism. The granules under consideration cannot be regarded as distinctive of any given disease, but simply as a degenerative manifestation of varied origin. Their importance resides in the fact that they may be present in considerable number before other symptoms of anæmia.

PLACENTAL TRANSMISSION.

THE placenta stands between the fœtal and the maternal organism, selecting from the blood of the latter the materials that are necessary for the growth and development of the embryo, and from the blood of the former those that are no longer useful and require to be eliminated. It may, therefore, be looked upon essentially as the respiratory and the nutritive, as well as the circulatory, organ of the fœtus. It is, however, probably, also the medium through which infection is occasionally conveyed to the fœtus from the mother, and through which the physiological effects of drugs administered to the mother are operative. From a review of the literature of the subject, Dorland (*American Gynæcological and Obstetrical Journal*, June, 1900) in a recent communication formulates the conclusion that while many drugs may be administered to the mother without any noticeable effect upon the fœtus, there are certain substances that show a special tendency to traverse the placenta, and, entering the fœtoplacental circulation, exert a positive influence for good or evil, according to the conditions that may be present in the given instance. Maternal medication, therefore, is indicated under certain circumstances, either in order to prevent the development of a similar condition in the fœtus, or to counteract the effect of germs and their toxins already introduced into the fœtal economy. The drugs that have been found to affect the fœtus in utero are notably opium, mercury, copper, lead, arsenic, and the iodides. In appropriate doses they may be administered to the mother in the

presense of suitable pathological conditions, with beneficial results to both mother and child. Any morbific influence acting upon the mother, either acutely, as in the case of the exanthemata, or more slowly, as in the case of tuberculous and syphilitic infection, will react deleteriously upon the product of conception, and either destroy it through its overwhelming toxic action, or render it feeble and less resistant to subsequent and post-natal invasion, or the disease will run an atypical course in utero with or without apparent vestiges at birth. The entrance into the fœtal structures is accomplished through the agency of the fœtoplacental circulation. It is probable that access is gained through bacterial action, the germs rendering the placental villi less resistant to invasion, whereby both the microbes and their toxins pass the natural barrier at the chorio-decidual junction. As a rule, the infectious diseases do not manifest their characteristic lesions in the fœtus, probably because of the passivity of its organs during antenatal existence. The germs, however, may be detected in large numbers by bacteriological and microscopic examination.

PRIVATE HOSPITALS FOR TRANSMISSIBLE DISEASE.

Many large cities are provided with public institutions to which it practically compels to be sent those suffering from contagious disease and unable to insure adequate isolation and disinfection at their homes. In other cities no provision at all is made for cases of this kind, or they must be sent to general hospitals, or even be kept at home. There is in every community a not inconsiderable number of persons whom, when seized with one of the diseases named, it would be desirable, if it be not absolutely necessary, to send to some institution in which the appropriate treatment shall be carried out, and who are both willing and able to pay for the service rendered. The public has begun to recognize that many ailments and many patients can often be better managed and better treated in well-regulated, well-organized, and well-disciplined hospitals than in private dwellings, however capacious and however sumptuous, and many are constantly availing themselves of the boon thus afforded by the private rooms of such institutions. Most general hospitals will not receive cases of contagious disease under any conditions, and there is, therefore, urgent need for such institutions as will admit those unfortunate enough to be thus attacked in hotels and boarding-houses, or while visiting in the homes of friends, and who do not wish and have no need to go to a public hospital. Hospitals of this special class are already in operation in Boston and New York, and a movement is on foot looking to the establishment of a pay-hospital for contagious diseases in Philadelphia. The objects to be fulfilled by this enterprise are so laudable and in such thorough harmony with current hygienic and preventive notions that there should be no difficulty in securing its speedy effectuation. The movement is, therefore, one to be most heartily encouraged, as it is also deserving of general emulation.

News of the Week.

Deaths from Heat.—During the excessive heat of the greater part of last week there were one hundred and twenty-five deaths of adults attributed directly to insolation, and the infant mortality was markedly increased.

First International Congress of the Medical Press.—This congress was held in Paris on July 26th, 27th, and 28th. The opening ceremonies took place in the Press Pavilion in the Exposition grounds, Professor Cornil presiding. In his opening address he referred especially to Virchow, who was present, as the dean of medical editors, who had been in harness for sixty years and had published in his *Archiv* much of the cream of German medical literature. He said that there were over three hundred medical journals published in France. M. Millerand, the Minister of Commerce, made a brief address welcoming the foreign representatives of medical journalism. M. Landouzy then spoke upon the history and the province of the medical press, and was succeeded by Virchow, who congratulated the Association of the French Medical press on having taken the initiative in organizing an international congress. He hoped that the creation of an international association might result from the congress, and said it was more in accordance with the dignity of medical journalism that it should have international congresses distinct from the medical congresses, and should not be relegated to an insignificant place as one of a multitude of sections of the triennial congress. The serious work of the congress was taken up the second day. The official delegates were presented and made short addresses: Drs. Posner for Germany, Ehlers for Denmark, Hansen for Norway, Gallet for Belgium, Brossi for Italy, Diakanoff for Russia, and Mendizabal for Mexico. Dr. Marcel Baudouin described his method of indexing original articles published in the medical press throughout the world, as exemplified in his new publication designed to take the place of the Index Medicus. The following papers were read and discussed: "The Legitimacy of Medical Advertising," by Archambaud; "Free Medical Journals," by Laborde and Romme; "Uniform Terminology for Scientific Classification," by de Maurans; "Reproduction of Photographs in Medical Journals," by Doyen and Aragon; "The Decimal System of Indexing," by Richet; "Relations between the Medical and the Political Press," by Rossi; "The French Law of Literary Property in its Relation to the Medical Press," by Pouillet, Rocher, and de Maurans; "Property in the Idea and in the Expression of the Idea in Medical Journalism," by Baudouin. On Saturday, July 28th, the following papers were read: "History of the Greek Medical Press," by Foustanos; "The Medical Press of Cuba," by Juan S. Fernandez; "History of the Belgian Medical Press," by Emile Gilson; "American Medical Journalism," by C. W. Fassett; "The Ethics of Medical Journalism in London," by Sprigge; "The German Medical Press," by Spatz; "The Right of Re-

production of Illustrations," by F. Alcan; "Medical Copyright," by Podoysotski; "The Right of Reply in the Medical Press," by Jayle and Pistre; "Professional Solidarity in the Medical Press," by J. Noir; "The Abuse of the Pseudonym Preceded by the Title Dr. in Medical Advertisements," by G. Lévy; "The Expediency of Founding an International Association of the Medical Press," by J. V. Laborde; "International Association of the Medical Press," by Posner. After some discussion it was decided to establish an International Association of the Medical Press, and to hold the next congress in 1901 in Brussels, on a date to be determined by the standing committee of the association.

The Danger of Disease in China.—Dysentery is the most dreaded of the diseases to which our troops in China, as well as in the Philippines, are exposed. The water is everywhere polluted, yet it is almost impossible to prevent troops on the march from drinking it unboiled and unfiltered.

"Sport."—A slugging-match between two brutes took place last week in this city, and the beaten man lay insensible for nearly five hours. It was briefly noted in the newspaper report "that the blow which the man received when his head struck the stage at the time of the knockout, together with the plexus blow and other severe body punishment, had brought him to a state of collapse, but that no serious results would be likely to occur." In the mean time the victor was receiving the homage of his devoted admirers. Evidently the "boxers" are not all in China.

The American Therapeutic Society was organized May 1, 1900, in Washington during the session of the Congress of American Physicians and Surgeons. "Reputable physicians, who are engaged in the regular active practice of medicine, and who are interested in the study of materia medica and therapeutics, in any or all their branches, and such reputable physicians not engaged in active practice but who are engaged in legitimate experimental therapeutic research, shall be eligible for active membership." The officers for 1900 are: *President*, Dr. Horatio C. Wood, of Philadelphia; *First Vice-President*, Dr. Howard H. Barker, of Washington; *Second Vice-President*, Dr. Reynold W. Wilcox, of New York; *Third Vice-President*, Dr. Eli H. Long, of Buffalo; *Secretary*, Dr. Noble P. Barnes, of Washington; *Recorder*, Dr. William M. Sprigg, of Washington; *Treasurer*, Dr. John S. McLain, of Washington. Applications for membership should be made to the secretary.

The Mississippi Valley Medical Association.—The twenty-sixth annual meeting of this association will be held at Asheville, N. C., October 9, 10, and 11, 1900, under the presidency of Dr. Harold N. Moyer, of Chicago. Dr. I. N. Love, of St. Louis, will deliver the address in medicine, and Dr. C. A. Wheaton, of St. Paul, Minn., the address in surgery. Negotiations are in progress by which the members of the association may obtain a one-fare rate for the round trip for this meeting. The association will not be divided into sections at this meeting. The headquarters will be at the Battery Park Hotel, at which place the sessions will be held. Those who intend to read papers are requested to send the title together with a brief synopsis of the paper to the secretary, Dr. Henry E. Tuley, 111 West Kentucky Street, Louisville, Ky.

The Congress of Spanish Surgeons, which was to have been held in September of the present year, has been postponed until 1901.

More Honors for the Prince of Wales.—At the meeting of the British Medical Association at Ipswich, the Prince of Wales, having already the double honorary qualifications of F.R.C.P. and F.R.C.S., was elected an honorary member of the association.

A Pediatric Society in Great Britain.—The Society for the Study of Disease in Children was inaugurated at a meeting held on July 24th at the rooms of the Royal Medical and Chirurgical Society in Hanover Square, London. The chair was taken by Dr. A. E. Sansom. There was a fair attendance of those interested in the movement. The secretaries of the new society are Mr. Sydney Stephenson and Dr. Charles H. Willey, and the treasurer is Mr. Clement Lucas. The society numbers about eighty members.

Rabies in Paris.—The annual report on hydrophobia, which has just been presented to the council of public hygiene by Prof. Adrien Proust, inspector-general of the board of health, shows by statistics that the number of mad dogs in Paris and the Department of the Seine is steadily increasing. The Pasteur Institute treated two hundred and ninety-four persons who had been bitten by rabid animals between January 1 and June 8, 1900.

Names of Scientists and Medical Men for the Hall of Fame.—The Senate of the New York University has submitted to the judges of the Hall of Fame a list of two hundred and thirty-four nominations, from which the final selection of one hundred names is to be made. The scientists whose names have been presented are John James Audubon, Spencer F. Baird, Alexander D. Bache, Nathaniel Bowditch, William Chauvenet, Henry Draper, James P. Espy, Asa Gray, Robert Hare, Joseph Henry, Edward Hitchcock, Isaac Lea, Matthew Fontaine Maury, Maria Mitchell, Benjamin Peirce, David Rittenhouse, Benjamin Silliman, Benjamin Thompson, and John Torrey. The physicians and surgeons are Valentine Mott, Benjamin Rush, James Marion Sims, Ephraim McDowell, and John Collins Warren.

Another Suit for Injuries Received in Hospital.—An amateur athlete living in Brooklyn has brought suit for $10,000 against the New York Hospital. He complains that while he was undergoing an operation under ether at the Hudson Street House of Relief his left heel was burned by the application of an overheated hot-water bag. He entered the hospital November 1, and because of the injury to his heel, he alleges, was kept there until late in November. He says that he was dismissed from the hospital before his heel was really well, and that it became much

worse and is still in such a state that he is not able to run races. The attorney for the hospital has filed an answer in which he says that in submitting to treatment in a charitable institution the patient waived all claims for damages resulting from purely accidental injury.

A Doctor Sued for an Automobile Accident.—A well-known physician in New Jersey has been sued for $25,000 damages for having caused the death of a woman by running into the wagon in which she was driving, with his motor carriage.

Mr. Treves' Diagnosis of Genius.—In an address recently made to the students of the London Hospital, Mr. Frederick Treves said that genius was nothing else than some form of neurosis, an untabulated nervous disease. Genius, he averred, never accomplished anything, but hard work would do all things, and if there was one profession in which geniuses were not wanted it was that of medicine.

Affairs at Home.—It is reported that there is a temporary improvement in the health of Cape Nome, the smallpox epidemic having been arrested, though there is still much sickness, chiefly pneumonia. It is feared, however, that this betterment is for only a short time, for there are four thousand stranded gold-seekers there who will be unable to get home without government assistance, and if they remain during the coming winter few will probably live to return in the late spring or summer.

"Revista de Medicina Tropical" is the name of a new monthly journal of Havana, published under the editorial management of Dr. John Guitéras, formerly of the University of Pennsylvania, and Dr. Emilio Martinez, assisted by Drs. Charles Finlay, Raimundo Menocal, Vicente de la Guardia, and Enrique Saladrigas. The first number, dated July, 1900, contains an introduction by Dr. Guitéras and some abstracts from foreign journals, but no original articles.

Phototherapy in Russia.—The dowager empress of Russia, who is by birth a Dane, has founded an institute in St. Petersburg for the treatment of lupus and other affections of the skin by means of light. It is modelled after Finsen's institute in Copenhagen, and is under the charge of a Russian physician who was sent by the empress to study the technique of phototherapy under Finsen himself. The matron is a Danish woman who has been a nurse in Finsen's institute and is thoroughly familiar with his methods.

Debt and Prosperity for Hospitals.—Sir William MacCormac said recently that no hospital can be satisfactorily carried on unless it is in debt, as there would then be no scope for charitable feelings and manifestations.

Scarlet Fever and Hotel Bills.—A man who had rented an apartment for himself and family in one of the large family hotels in this city recently vacated it, alleging that he was constructively evicted by the occurrence of scarlatina in the house. The hotel company sued him for the unpaid rent and has recovered in the supreme court. It was not shown, the court said, that the management had been negligent in the case, but it had been demonstrated that all possible precautions had been taken to prevent the spread of the disease. It could not, therefore, be held that there was an eviction in fact or in law.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the medical corps of the United States navy for the week ending August 11, 1900. August 3d.—Assistant Surgeon C. A. Crawford detached from the *Eagle* and ordered to the *Chesapeake*. August 6th.—Assistant Surgeon C. H. Delancy detached from the *Constellation* August 13th, and ordered to the *Bancroft* August 14th. August 9th.—Passed Assistant Surgeon W. C. Braisted detached from the *Massachusetts* and ordered to the *Topeka* August 15th. Assistant Surgeon W. M. Garton detached from the *New York* and ordered to temporary duty on the *Massachusetts*. Passed Assistant Surgeon James Stoughton, U.S.N., was drowned at Shanghai, China, August 5, 1900.

Obituary Notes.—Dr. John Francis Burns, visiting surgeon of St. John's Hospital in Long Island City, died in that institution August 9th, of spinal meningitis, aged thirty-seven years. Dr. Burns was born in New York City and graduated from the University of New York in 1889. Three years later he opened an office in Long Island City.

Dr. Cortland Van Rensselaer Creed, a well-known negro physician of New Haven, died suddenly on August 8th, of Bright's disease. He was graduated from the Yale Medical School in the class of 1857. He was about sixty-seven years old.

Dr. Elias B. Harris died recently at Virginia City, Nev., at the age of seventy-five years. He was born at Richmond Plains, N. Y., and was graduated from the medical department of the New York University in the class of 1847.

Dr. Samuel H. Gish died at his home in Janesville, Wis., on August 2d, at the age of seventy-nine years. He was born in Lancaster County, Pa., and was graduated from the Philadelphia Medical College in 1851. He practised for several years in Elizabethtown, Pa., and then took up the study of dentistry and practised the same in Janesville to within a few weeks of his death.

Dr. Carl M. Kelley, coroner of Pike County, Pa., fell dead at his home in Matamoras on August 11th, of heart trouble. He was born at Scranton thirty-eight years ago. He was graduated from the College of Physicians and Surgeons in Baltimore in 1883, and entered Bellevue Hospital, New York. He practised in Scranton, then in New York, and settled in Matamoras two years ago. His father was Dr. Thomas Kelley, of Scranton, and both of his grandfathers were physicians. He had five brothers in the medical profession, two of whom are living.

Dr. Henry J. Costello, of Philadelphia, killed himself on August 13th at Eaglesmere, by hanging. He had suffered for a long time from insomnia. He was twenty-eight years old and was a graduate of the Jefferson Medical College in the class of 1895.

Reviews and Notices.

Neuroma and Neurofibromatosis. By Alexis Thomson, M.D., F.R.C.S.E. 168 pages quarto; twenty plates. Edinburgh: Turnbull & Spears. 1900.

The author of this book is certainly to be congratulated for this interesting contribution to medical literature. The subject-matter is clearly and concisely treated, and increased value is given to the work by the citation of numerous clinical records of this disease. The illustrations are numerous and particularly apt and good.

"Festschrift" in Honor of Abraham Jacobi, M.D., LL.D., to Commemorate the Seventieth Anniversary of His Birth. New York: The Knickerbocker Press. 1900.

An American jubilee volume of international contributions to medical literature is among the rarest of rare things that come to the editor's table. The one before us does the highest credit to all those who, in its conception and execution, had a part in presenting to the profession a work which, while it honors Professor Jacobi, reflects honor upon themselves. Scientific contributions from all parts of the world are published in English, German, and French. There are a number of good illustrations. The frontispiece, a portrait of Dr. Jacobi, especially made for this work by the celebrated etcher James D. Smillie, is truly a work of art and a most excellent likeness.

The Refraction of the Eye: A Manual for Students. By Gustavus Hartridge, F.R.C.S., Senior Surgeon to the Royal Westminster Ophthalmic Hospital; Ophthalmic Surgeon and Lecturer on Ophthalmic Surgery to the Westminster Hospital; Ophthalmic Surgeon to St. Bartholomew's Hospital, Chatham; Consulting Ophthalmic Surgeon to St. George's Dispensary, Hanover Square, etc. With one hundred and five illustrations. Tenth edition. Philadelphia: P. Blakiston's Son & Co. 1900.

The revised tenth edition of this excellent work forms a volume of two hundred and sixty-seven pages; it is carefully written and treats the subject in quite a comprehensive manner. The language is simple and direct and of a nature readily understood by the student. Illustrations are found wherever they can serve to elucidate the text. Cases presenting the various problems in refraction are given as required. The dioptric system of lens nomenclature is used throughout the work, the relative value of the inch systems being given in an appendix. A creditable series of test types is added. This work has few equals as a guide for the student in the study of refraction; its teachings are thoroughly trustworthy.

The Ophthalmic Patient. Manual of Therapeutics and Nursing in Eye Disease. By Percy Friedenberg, M.D., Ophthalmic Surgeon to the Randall's Island and Infants' Hospitals; Assistant Surgeon, New York Eye and Ear Infirmary. New York: The Macmillan Company. 1900.

This little volume of three hundred and eleven pages is a comprehensive treatise on ophthalmic nursing, and is designed "to serve as a practical guide to physicians, students, and nurses who lack special training in the care of ophthalmic cases." The contents include instructions regarding the construction of eye wards; method of taking histories; diet and dress of patients; remedies used in ophthalmic practice; asepsis and antisepsis; preparation of patients for operation, and post-operative care; anæsthetics; the care of instruments, dressings, and bandaging, etc. The language is sufficiently devoid of technical terms to be readily comprehended by one who has not had a medical education. The work is admirably adapted to the use of nurses and contains much that is of value to every practitioner of medicine.

Injuries to the Eye in their Medico-Legal Aspect. By S. Baudry, M.D., Professor in the Faculty of Medicine, University of Lille, France, etc. Translated from the Original by Alfred James Ostheimer, Jr., M.D., of Philadelphia, Pa. Revised and Edited by Charles A. Oliver, A.M., M.D., Attending Surgeon to the Wills Eye Hospital; Ophthalmic Surgeon to the Philadelphia Hospital; Member of the American and French Ophthalmological Societies, etc. With an Adaptation of the Medico-Legal Chapter to the Courts of the United States of America, by Charles Sinkler, Esq., member of the Philadelphia Bar. The F. A. Davis Company. 1900.

This small volume of one hundred and sixty-one pages is divided into four parts. Parts I. and II. are devoted to an enumeration and brief description of the injuries that may occur to the eyeballs and adnexa, and their treatment. Part III. treats of the simulated and exaggerated affections of the eye and fully describes the methods for their detection. Part IV. contains a description of medico-legal expert testimony, with a brief discussion of the subject and some illustrative cases. A fairly comprehensive bibliography is appended.

A Practical Treatise on the Sexual Disorders of the Male and Female. New (second) edition. By Robert W. Taylor, M.D., Clinical Professor of Venereal Diseases in the College of Physicians and Surgeons, New York. In one handsome octavo volume of 435 pages, with 91 illustrations and 13 plates in colors and monochrome. Philadelphia and New York: Lea Brothers & Co. 1900.

The author is to be congratulated upon the popularity which exhausted his first edition so promptly. This issue has been carefully revised and some new matter added, especially in chapters dealing with female diseases, including vaginismus, kraurosis vulvæ, etc. To the original illustrations some additions have been made, so that in its present form it will be more than ever valuable to those in search of knowledge in these departments.

Atlas and Epitome of Special Pathological Histology. By Docent Dr. Hermann Dürck, Assistant in the Pathological Institute, Prosector to the Municipal Hospital L. I. in Munich. Authorized Translation from the German. Edited by Ludvig Hektoen, M.D., Professor of Pathology in Rush Medical College, Chicago. Circulatory Organs; Respiratory Organs; Gastro-Intestinal Tract. With sixty-two colored plates. Philadelphia: W. B. Saunders. 1900.

The author of this volume gives in a concise manner the main points to be noted in the different diseases of the circulatory, respiratory, and digestive organs. The plates are good, made from the original specimens of the author, and are particularly selected as best illustrating the topics under discussion.

Fractures. By Carl Beck, M.D., Visiting Surgeon to St. Mark's Hospital and to the New York German Poliklinik; formerly Professor of Surgery, New York School of Clinical Medicine; Consulting Surgeon, Sheltering Guardian Society Orphan Asylum, etc. With an Appendix on the Practical Use of the Roentgen Rays. Philadelphia: W. B. Saunders & Co. 1900.

This work is important chiefly as being the first attempt to bring before the profession in a systematic way the study of fractures by means of the Roentgen rays. The author has shown by skiagrams, chiefly original, all the common and many of the rare forms of fractures. The use of the Roentgen rays with its full technique is fully explained, and the practical points (especially the errors liable to cause misinterpretations) are brought out with a thoroughness which merits high praise. To any one who intends to deal with fractures and has the privilege of an *x*-ray apparatus, the work can be recommended as useful and trustworthy. There are one hundred and seventy-eight illustrations.

A Treatise on Appendicitis. By John B. Deaver, M.D., etc. Second edition, revised and enlarged. Illustrated with twenty-two full-page plates. Philadelphia: P. Blakiston's Son & Co. 1900.

This volume is an enlarged and revised edition of the author's work of four years ago. He is more than ever convinced that the treatment of appendicitis is a purely surgical question, and he maintains the correctness of his very radical views with considerable success. The chapters on the pathology of the disease in question are instructive, and that on differential diagnosis is complete and useful. The subject of medical treatment is given some space, and we are warned in this connection that surgical treatment is at any time likely to be imperatively demanded by the occurrence of threatening symptoms. This is, of course, entirely true, and only shows what a makeshift the medical treatment of appendicitis is. The plates in this volume are very well executed and its general appearance is excellent.

A Manual of Clinical Diagnosis by Means of Microscopic and Chemical Methods, for Students, Hospital Physicians, and Practitioners. By Charles E. Simon, M.D., Late Assistant Resident Physician, Johns Hopkins Hospital, Baltimore; Fellow of the American Academy of Medicine. Third edition, thoroughly revised. Illustrated with one hundred and thirty-six engravings and eighteen plates in colors. Philadelphia and New York: Lea Brothers & Co. 1900.

The third edition of this valuable work is brought thoroughly up to date. The most approved modern methods are described comprehensively, yet clearly and simply.

The section on the study of the blood has been elaborated, and the whole work has been carefully revised, much new material being added. The subject-matter comprises the examination of the blood, the secretions of the mouth, the gastric juice and contents, the fæces, the nasal secretion, the sputum, the urine, transudates and exudates, cystic contents, cerebro-spinal fluid, the semen, the vaginal discharge, and milk. The text is embellished throughout with excellent illustrations.

Les Sanatoria. Traitement et Prophylaxie de la Phtisie Pulmonaire. Par S. A. Knopf, de la Faculté de Paris et de Bellevue Hospital Medical College (New York), Médecin du Département Pulmonaire du New York Throat and Nose Hospital; Ancien Assistant du Professeur Dettweiler au Sanatorium de Falkenstein; Membre de l'Académie de Médecine de New York; Lauréat de l'Académie de Médecine de Paris. Deuxième edition. Paris: Georges Carré et C. Nand. 1900.

The second revised and greatly enlarged edition of this work, which was originally the author's graduation thesis at the University of Paris, is an attractive treatise of four hundred and eighty-five pages, profusely illustrated and handsomely bound—indeed, a veritable édition de luxe. The author emphasizes the importance of hygienic and dietetic measures in the treatment of tuberculosis, and he lays great stress on prophylaxis in this disease. In the chapter on aerotherapy there is a detailed description of the pneumatic cabinet. The most important sanatoria in the different countries are described with illustrations. The last two chapters deal with maternity sanatoria, hospitals and schools for tuberculous children, and sanatoria for the poor. Dr. Knopf is the author of an American publication on the same subject, to which was awarded in 1898 the Alvarenga prize of the College of Physicians of Philadelphia, and he has just received a prize established by the Berlin Congress of Tuberculosis for a treatise on the best method of combating tuberculosis among the poor; this will be published by the committee of award in Berlin, so the author will enjoy the unique distinction of having written and published three books in three different countries, of which two have been officially proclaimed by competent judges the best of their class.

Die angeborene Luxation des Huftgelenkes. Von Geh. Med.-Rath Prof. Dr. Max Schede (Bonn). 26 pages quarto, with 8 plates. Hamburg: Lucas Gräfe & Sillem. 1900.

This short monograph is certainly a most valuable addition to the subject of congenital hip-joint dislocation. A number of points brought out by the author differ radically from what have been the hitherto accepted notions concerning this subject. First, the author insists that by far the most frequent type of congenital hip-joint dislocation is the supra-cotyloid, and not the iliac; thereby differing from traumatic hip-joint dislocations. This difference is due to the fact that the femur head in congenital dislocations leaves the cotyloid cavity at the upper aspect of the capsule instead of at the posterior inferior aspect, as it usually does in traumatic dislocations. In an excellent chapter, "On the Changes in the Head and Upper Extremity of the Femur," the author has drawn especial attention to an anteversion of the head, which is present in most of these cases. In virtue of this anteversion the head no longer lies medially to the trochanter, but in front or even, in extreme cases, external to it. This change in the upper end of the femur interferes with the success of reposition and final healing, if these are carried out in a manner applicable to traumatic cases of hip-joint dislocation. The author has therefore modified the method of reposition and after-treatment. His method may be summarized as follows: (1) By palpation and Roentgen photography in various positions of the hip joint, the extent of anteversion of the upper femur end is determined. (2) Reposition is accomplishd by traction (sixty to one hundred pounds), and while pressure over the trochanter is being made, the limb is abducted and rotated inward. When the anteversion of the upper femur end is very slight, outward instead of inward rotation is made. Inward rotation is maintained, the extent of the rotation depending on the amount of the anteversion. (3) The limb is immobilized in the position of abduction and inward rotation for from two to three months, and then to prevent a reluxation, which usually follows when outward rotation is assumed, an osteotomy of the femur through its lower third is performed. The lower fragment can thus be brought into its normal anterior position, while the upper fragment is kept inwardly rotated—healing occurs in this position. (4) After the osteotomy has healed the patient is required to wear a plaster-of-Paris splint for from three to six months. The monograph is excellently illustrated by numerous Roentgen photographs.

Progress of Medical Science.

New York Medical Journal, August 11, 1900.

The Relation of Seminal Vesiculitis to Impotence.—Ramon Guitéras says that seminal vesiculitis results from prostatic trouble due to acute prostatitis, in which the ejaculatory ducts are pressed upon by an exudate in the gland; prostatic abscess, during the healing of which the ducts may be caught and pinched in the scar tissue, and any growth or enlargement of the gland in so far as it presses upon them. Pressure from any of these causes interferes with the function of the vesicles, and causes inflammation of them, in much the same way that an obstruction of the urethra gives rise to cystitis. Cases generally present a stage of sexual excitation followed by depression. The vesicles are sensitive to touch. They may be dilated and in a condition which might be termed spermatic retention due to an atonic condition of the walls associated with pressure; at other times they are dilated, but feel soft and pasty; again there may be an acute inflammation of these structures, or the condition may be one of atrophy. The method of treatment may be outlined as follows: Internal remedies to neutralize the urine in cases of over-acidity; rectal irrigation every night, with decinormal salt solution or strained flaxseed tea at a temperature of 105 to 120 F., by means of the double-current rectogenital tube, and massage of the internal genitals every five days, followed immediately by a urethral irrigation whenever there is chronic prostatitis or posterior urethritis associated with this condition. The patient will at first scarcely be able to tolerate the gentlest manipulation of the vesicle by the finger, but after several séances not only will he be able to endure the massage, but he will feel much benefited and relieved by it. After the symptoms of inflammation and irritation have been relieved, tonics, such as strychnine and iron, can be used, or even damiana and phosphorus. Electricity may also be employed by means of the rectal electrode, using the galvanic or the faradic current or, better still, the galvanic followed by the faradic.

The Diagnostic and Therapeutic Value of Insufflation of the Œsophagus, Stomach, and Colon.—C. D. Spivak describes the different methods of producing insufflation, and gives the differential diagnosis of the various conditions it is used to detect. The procedure has been recommended in obstruction of the bowel, especially in invagination and volvulus, in chronic atony of the bowel, etc. Spivak is experimentiug with the introduction of hot air into the stomach for various gastric disorders, but is not yet ready to report results.

The Spectacle and Eyeglass Habit.—A. W. Herzog criticises severely an article which recently appeared in the *Journal* from the pen of N. B. Jenkins. The tone of the article in the present issue is not pleasant, although the author evidently means well. Jenkins' contention was in the main that glasses were often worn when there was no necessity for them. Herzog maintains that glasses are worn not alone for imperfect vision, but relieve many reflex neuroses, such as headache, nervousness, chorea, etc.

An Investigation into the Causes of So-Called Uric-Acid Lesions and a Rational Therapeusis of the Uratic Diathesis.—By A. C. Crofton.

The Etiology of Diphtheria and the Value of Antitoxin; A Further Criticism of Dr. Herman's Views.—By A. Robin.

Obstetrical "Don't Fails."—By C. I. Page.

Medical News, August 11, 1900.

Anastomosis of Ureters with Intestine.—Reuben Peterson, basing his paper on experimental work, reviews *in extenso* the literature of the subject. The most striking fact revealed by such study is the exceptional high mortality accompanying the operation. Primary mortality is large by all methods; twenty-eight uretero-intestinal implantations show a primary mortality of thirty-two per cent. The general conclusions are as follows. (1) The primary mortality of uretero intestinal anastomosis both in experimental work on animals and in man is exceedingly high. (2) The best technique is that requiring the least amount of suturing of the ureters themselves. (3) All efforts to prevent ascending renal infection in animals or in man when the ureter has been implanted without its vesical orifice have proved futile. (4) It is impossible to determine in advance the extent of the infection which will result from uretero-intestinal anastomosis. The patient may die in a few days of a pyæmia or in a short time of pyelonephritis, or, in rare cases, may recover from the infection with resulting contracted kidneys. (5) Hence the operation is unjustifiable, either for the purpose of making the patient more comfortable, as in exstrophy of the bladder, vesico-vaginal or uretero-vaginal fistula, or for malignant disease of the bladder. (6) The results of uretero-

intestinal anastomosis through the formation of vesico-rectal fistulæ have not been favorable up to the present time. (7) The success of Frank's experimental work in vesico-rectal anastomosis justifies the expectation that the future results of this operation will be more satisfactory. (8) The primary mortality of uretero-trigono-intestinal anastomosis is low for an operation of this magnitude. (9) While it cannot be denied that ascending renal infection may occur after this operation, the infection as a rule is of such a type that the chances of the individual's overcoming it are good. (10) Hence, the operation of implanting the vesical flap with its ureteral orifices into the intestine is a justifiable surgical procedure. (11) There is no valve guarding the vesico-ureteral orifice; nor does the circular muscle-layer of the ureter nor the bladder-muscles themselves act as a sphincter. (12) It has been abundantly demonstrated by experimental and clinical work that the rectum tolerates the presence of urine and acts as a good substitute for the bladder, and that good control over the anal sphincter will be maintained.

Chronic Enteritis and Tuberculous Enteritis Treated with Hypodermic Injections of Arsenic.—Louis Kolipinski says pathological anatomy recognizes: (1) a hyperplastic inflammation of the mucous membrane; (2) an atrophic form; (3) ulceration of the mucosa may coexist. Injections are given once a week in chronic enteritis; a 0.5-per-cent. salt solution being used as a menstruum. If good results are not to be noted within fourteen days, the injections may be abandoned. The conclusions quoted are: (1) The arsenical injection is safe, painless, and effective. (2) The dose is very small. From gr. $\frac{1}{12}$ to gr. $\frac{1}{8}$ of sodium arsenite is sufficient. (3) One, two, or three injections per week will cure in the milder cases. (4) Other internal medication is avoided, and the patient has no daily routine of dosing. (5) Greater latitude in diet can be allowed without detriment.

Vaccination Eruptions.—Jacob Sobel makes a sharp distinction between eruptions incidental to the period following vaccination and those due to the inoculation pure and simple. The paper deals mainly with generalized vaccination eruptions. The material studied was that of Dr. C. W. Allen's skin clinic during three years, in which there were out of 4,160 vaccinations 583 sequelæ or complications, of which 80 were generalized eruptions of one kind or another, or about two in every hundred. Illustrations of the urticarial bullous and vesico-bullous types accompany the article. The most common generalized eruption after vaccination is the urticarial, occurring from the fifth to the fifteenth day.

The Automobile in Country Practice.—By A. D. Hard.

School Break-Down.—By J. Henry Bartlett.

Boston Medical and Surgical Journal, August 9, 1900.

Acute Dilatation of the Heart in Influenza of Children.—F. Forchheimer describes two forms of this affection, as seen in epidemics of influenza, a severe and a mild form. The dominant symptoms are on the part of the heart, with a peculiar respiration which the author has seen in only two other conditions—in pericardial effusion, and the fugitive œdematous condition of lung that frequently precedes pneumonic consolidation in influenza without cardiac change. He believes that we are justified in assuming that one form of heart dilatation is produced by the action of the toxin upon the nervous system of the heart and possibly upon the myocardium; this form, according to the observations made by West, may end fatally. The second form occurs when the outflow of the blood is materially interfered with by mechanical conditions. This lasts much longer than the first, but in children has a tendency to recovery.

The Progress of Medicine.—By Harold C. Ernst.

The Philadelphia Medical Journal, August 11, 1900.

Puerperal Eclampsia.—J. B. Todd says that headache during labor and the two following days is a danger signal of coming eclampsia. In the treatment he places little reliance on diuretics, but gives hydragogue cathartics, preferably elaterium, to effect the elimination of the poison. Morphine in doses of gr. ss.–iss. is given hypodermically to control the convulsions, the injection being repeated whenever the patient complains of severe pain in the head. The cathartic is followed by a mixture of one grain of corrosive sublimate and one ounce of tincture of the chloride of iron, twelve drops being given in a capsule every four hours. The writer reports briefly ten cases which occurred in his practice.

Journal of the American Medical Ass'n, August 11, 1900.

The Treatment of Acute Alcoholism by Large Doses of Digitalis.—W. S. Loomis finds it interesting to note that a drug the use of which even in moderation is supposed to be attended with some danger can be given in dose of one-half ounce of the tincture in alcoholism without producing any of the ordinary symptoms of poisoning. From a study of cases treated by this method the following conclusions are drawn: (1) The indiscriminate use of large doses (half-ounce) of digitalis in acute alcoholism is fraught with danger. (2) The cases in which it should be given are the strong, robust, those in early life, with no complications, and those with violent delirium. In these cases the result will be exceptionally favorable. The patients become quiet and go to sleep with a certainty and promptness obtained by no other methods with which the author is familiar. (3) If after three doses no narcotic effect is noted, he would not advise a continuance of the remedy. He believes in the above class of cases it can be used with perfect safety for a limited number of doses. (4) The failures among the writer's cases were in the chronic alcoholic subjects, in those in middle and advanced life, in the anæmic, and in those with bad nutrition. (5) One fact noted which showed marked results from the treatment was that when the patients recovered and awoke from their sleep they were in such good condition that they were able to leave the hospital at once. This is an unusual experience, as ordinarily convalescence is delayed for two or three days.

New Sources of Danger in the Use of Opium.—T. D. Crothers refers to his former paper bearing on the question of differing effects of opium in different individuals and the tendency created in some persons. He finds the stimulating effect fascinating to the alcoholic, necessitating watchful care in the use of any form of opium in these or other subjects. The facts to make prominent are: (1) The use of opium continuously for any possible purpose is dangerous, in that it may impress the organism in some unknown way and leave a diathesis and susceptibility to resort to it again in after-life. (2) The condition called opium addiction, in which the drug is used for its narcotic and pleasing effects, is one of organic disease whose origin is preventable by a study of the conditions and peculiarities of the person in early life. (3) When opium is used with but little, if any, irritant effects, there exists a predisposition to its continuous use and the development of an addiction. (4) When its poisonous effects are marked in the irritations and exaltations which follow its use, there is great danger of organic changes and diseases with fatal results. (5) The psychic element in these cases furnishes very suggestive hints of the derangements which follow the mental perversions and disturbances of reason and judgment, and gives some idea of the profound organic changes which take place.

Scrofulous Keratitis.—H. Gradle makes observations on the etiology and treatment of this condition, especially by salicylate of sodium. They define the conditions generally included under the term by writers, and give the present clinical conception of scrofula. The exciting cause of phlyctenular eruptions is unknown, but their peculiarities are dwelt upon. Salicylate of sodium, best given in five-grain tablets, shows its good effects, if at all, within two days. Its value was most marked in cases accompanied by much suffering.

Fracture and Dislocation of the Spine.—S. P. Kramer gives a report of a case of gunshot wound of the spine, pointing out the difficulties and describing measures for the restoration of function in the cord. Non-operative treatment is not favorably considered, extension is too risky, while the need of early operation to remove pressure is urgent.

Secondary Glaucoma.—W. C. Posey and E. A. Shumway give a clinical and pathological report of three cases representing different types of the disease. They define secondary glaucoma and give report on the microscopic findings, calling attention to points of special interest.

Some Remarks upon the Technique of Operations Designed to Cure Radically Oblique Inguinal Hernia.—F. D. Bird lays stress on the following points: the skin incision to be made well above Poupart's ligament and well away from the pubes, the separation of the fibres of the external oblique aponeurosis at a suitable spot, the separation being carried well toward the muscular portion; the sparing of the external ring; the dislocation but partial of the cord from its bed, and the elimination of the sac from above and therefore the preservation of the nerves, the whole to be accomplished with little or no bleeding—an advantage to be attained with great gentleness and the use of dissecting forceps. Apart from the unworkmanlike appearance of a sloppy operation area, bleeding much inconveniences the surgeon and damages the tissues. It obscures the view, necessitates constant sponging, and irritates the delicate areolar planes, which become more or less loaded with blood not capable of being removed. The serous exudation is much greater and the tissues are much weaker and sodden. In addition to these immediate disadvantages there is the grave though unlikely occurrence of thrombosis in the veins of the cord with its possibilities of pneumonia and other distant disasters. The absence of the deep sutures is a gain in two directions: the unimpeded muscle acts as nature meant it to, and there is no foreign body at all in the depths of the wound, no silk with tension on it, and no over-chemicalized catgut.

A Note of the Safest Method of Removal of the Appendix.—A. A. Warden advocates Doyen's method, which he describes as follows: The little mesentery of the appendix is first ligatured with a small silk ligature to free the appendix laterally. Then (1) the base of the appendix is gently crushed with Doyen's small clamp. Almost any forceps suffices for this purpose if strong enough and broad enough completely to occlude the appendix for a breadth of, say, a quarter of an inch; (2) a fine silk ligature is thrown round the base of the appendix in the furrow left by the clamp; (3) the appendix is then removed by the thermo-cautery cutting close to the ligature; (4) a purse suture is then made in the serous covering of the cæcum close round the base of the appendix (as this purse-stitch is drawn tight the little stump is invaginated so that all is completely closed); (5) for safety a second fine silk purse-stitch is made and the little pucker of the first stitch is similarly invaginated and the ligature is gently tightened. The result technically is perfect, and certainly this is the most aseptic method of removing the appendix.

A Case of Meningo-Myelitis with Bacteriological Examination of the Spinal Cord.—G. R. Murray and W. Hardcastle report this case. The patient was a single man aged twenty-nine years, who died seven and a half weeks after admission to the hospital. The attack seemed to have been precipitated by wetting, exposure, and fatigue. The characters of the micro-organisms obtained from the spinal cord are summarized as follows: A short oval motile bacillus which stains readily by aniline dyes, the stain in many cases showing a much stronger affinity for the ends than for the centre of the bacillus. It can with care be stained by Gram's method, and was found in large numbers in the pia mater and also in lesser numbers in the substance of the cord. Pure cultures of the bacillus were obtained both from the meninges and also from the substance of the cord itself. Subcutaneous inoculation caused rapid general infection in the guinea-pig and a local infection in the rabbit. The bacillus grows readily on the ordinary nutrient media in both the hot and cool incubators. It liquefies gelatin.

A Blood Reaction in Diabetes Mellitus; its Cause and Diagnostic Value.—R. T. Williamson says that a drop of blood taken from the finger of a diabetic decolorizes a warm alkaline solution of methylene blue when mixed in certain proportions (details given), while blood from healthy persons or from individuals sick with other diseases causes under the same test conditions no such decolorization. The action is due to the glucose in the blood. The test is available in coma when the bladder may be empty, and may be of medico-legal value in ascertaining the cause of death in a doubtful case. It has been made with positive results sixteen hours after death.

A Case of Sudden Death Shortly After Operation.—W. B. Thompson operated for adenoids and enlarged tonsils on a child aged twelve years, chloroform being used. The child did well for a few minutes, when it began to be cyanotic with weak pulse, dilated pupils, and feeble respiration. The usual restoratives, lingual traction, and finally tracheotomy were all made use of, but without avail. There was no attempt at rallying, and heart sounds and breathing ceased for some time after artificial respiration was abandoned, after about one and one-half hours. Death was ascribed to gradual cardiac paralysis.

The Etiology of Scurvy.—W. E. Home suggests that scurvy is essentially an infection of the mouth with micro-organisms out of decayed food, antagonized by lime-juice and fresh vegetables which act as antiseptics, this infection of the mouth being most apt to occur in times of hardship when cleanliness is least within our reach.

Berliner klinische Wochenschrift, July 23 and 30, 1900.

The Etiology and Therapy of Tabes Dorsalis.—Concerning the relation of syphilis to tabes, P. K. Fels takes the view that the former makes a predisposition for the latter, or that the latter may be regarded as a para-syphilitic affection comparable to the paralysis following diphtheria. The exact relation of the two affections is, however, still undetermined. Tabes more often follows syphilis when the manifestations of the latter have been mild, and it does not occur until from five to fifteen years after the specific infection. It is not a continuance of the original syphilis. Concerning treatment Fels says that the best treatment is the prophylactic—not to become syphilitic. Any plan of therapy should aim at putting the general nervous system into the best possible condition. Mercury is to be given not as a routine but only in selected cases. It is indicated (1) in cases showing specific evidence; (2) when tabes comes on only a few years after infection and when previous treatment has been without result; (3) in cases showing an unusual clinical course which gives evidence that the cord and brain are involved. For bladder and sexual weakness, Fels recommends strychnine given subcutaneously in the general region of the bladder. He regards the effect of the chloride of gold and sodium as problematical. Protargol is of service. He also enumerates the various other remedies and plans of treatment which have been at various times tried.

The Recognition and Treatment of the Anæmias.—H. Senator calls attention to the much wider signification given to the term "anæmia" in recent years, and alludes in brief to the different conditions now included under this clinical term. In arriving at the etiology of a given case we should never omit to examine both macroscopically and microscopically the stools with reference to the presence of parasites and of blood. In all severe cases, the blood should be examined with reference to departures of cell contents from the normal. Finally, we may find the cause of some cases to reside in impairment of the chemical and motor functions of the stomach. In many cases of chlorotic anæmia, the use of the alkaline salts will give far better results than to begin at once with iron preparations. When the time for the latter may arrive, combinations with the organic acids as lactic, citric, acetic, etc., will answer better than the metallic compounds, for they are less liable to upset the stomach and to constipate. He places much confidence also in the "sweat-cure" by means of internal remedies and water, sand, and air baths. He also alludes to essential pernicious anæmia, and to that form which comes from residence in mountainous regions.

Systemic Infection in Diseases of the Urinary Organs.—Posner and J. Cohn exposed the ureter in rabbits, and injected into the central portion cultures of various organisms. The wound was then carefully closed under strict antisepsis. In seventeen cases peritonitis resulted three times. Out of the remaining fourteen, three inoculations with the bacillus anthracis all proved fatal; negative results were obtained with the bacillus prodigiosus in some cases, while in two cases resulting fatally from peritonitis there was a general infection. The staphylococcus aureus and albus and the streptococcus gave in every instance positive evidences of infection, except in one instance of inoculation with the latter, in which the authors ascribe the failure to a faulty technique.

Phenylhydrazin in Anæmia.—S. Kaminer and R. Rohnstein discuss the question as to whether or not pernicious anæmia is a true hæmoglobinæmia, and claim that in the muriate of phenylhydrazin we have a substance which in experimentation on animals produces blood disturbances identical with those of Biermer's anæmia. The article is devoted to a recital of the work done by the authors along the line indicated, and a detailed account is given of the blood changes as found by them.

Contributions to Tetanus Intoxication.—Miyamoto describes a form of death caused by tetanus infection which does not run the usual course. Rabbits, when inoculated under some conditions, do not exhibit the characteristic cerebral and spinal manifestations of the destructive action of the poison on the nervous elements, but gradually succumb to a progressive marasmic emaciation. This modification of the pathological picture, to which the name of "tetanus sine tetano" has been given, might seem explicable on the ground of the theory advanced by Ehrlich that the toxin produced by the specific micro-organism is made up of two components. To one of these, "tetanospasmin," the convulsive symptoms are due, while the other has the property of destroying red blood cells and has been named "tetano-lysin." That the "tetanus sine tetano" is not due to the action of this latter body is, however, shown by the author's experiments with an old specimen of the tetanus toxin which produced the marasmic form of the disease, but did not have the property of modifying red blood cells. The conclusion is, therefore, drawn that the modified tetanus produced was the result of a double decomposition of both toxic elements, accompanied by the formation of a third poisonous "toxon" body.

Are Spontaneous Fractures of the Metatarsus to be Regarded as Accidents?—Muskat's article has reference to a point in dispute between claimants for damages and accident insurance companies. Even when none of the predisposing causes to spontaneous fracture are present, such as bony atrophy either senile or occurring in youthful individuals as a result of wasting disease or maladies of the central nervous system, particularly tabes and paralysis, acute osteomyelitis, terminating either in abscess or necrosis, caries (tuberculous), rachitis, osteomalacia, sarcoma, carcinoma, enchondromata and cysts, echinococcus, syphilis (rare), scurvy (rare), or hereditary tendency without known cause, sudden exertion or strain in jumping, alighting from street-cars, etc., may produce a slight incomplete fracture of one of these bones, well protected as they seem. This slight injury usually passes unnoticed till at some other time the break suddenly becomes complete, and what is apparently a spontaneous fracture is produced. It is, however, evident that this is not truly so, and that the case is properly to be considered as one of accident, for which insurance may be collected.

Two Cases of Cerebellar Tumor.—Schede discusses the complicated symptomatology attending growths in this situation, and concludes that definite location of the neoplasm with a view to operation is as yet impossible. The fact that the tumor is situated in the cerebellum may usually be determined without especial difficulty, but we are still unable to predicate with accuracy on which side the skull should be laid open. The only sign which appears to be even relatively useful is that in many cases the tendency seems to be for the staggering gait to be most pronounced toward the side opposite to that occupied by the new growth. The literature contains records of eleven cases operated on; of these patients five succumbed to hemorrhage and shock, two survived the operation but manifested no signs of improvement, and only two permanent cures are chronicled. The author describes two cases operated on by himself with apparently complete relief of the symptoms in one, while the other patient, owing to the fact that complete removal was impossible, died of the primary growth in a short time.

Investigations on the Parasitical Nature of Eczema.—By Scholtz.

Münchener medicinische Wochenschrift, July 24, 1900.

The Newer Experimentally Determined Methods for the Diagnosis and Treatment of Diseases Caused by Auto-intoxication.—Blum publishes the following conclusions. (1) Certain definite poisons are continually being generated within the organism and are normally destroyed by the thyroid gland. (2) These poisons originate in the intestinal canal, and in their character and quantity depend, on the one hand, on the nature of the decomposing albumins present, and, on the other, on the bacteria of decomposition. (3) If the activity of the thyroid gland is impaired and these entero-toxins are able to act unhindered on the organism, severe disturbances accompanied by anatomical changes are produced. (4) Such animals as either with or without treatment remain well, or recover from illness after removal of the thyroid gland, possess in their blood bodies protective against these entero-toxins. (5) The entero-toxins which are taken up in their passage through the thyroid gland are deposited there as thyreotoxalbumin and gradually rendered harmless. (6) There is both a natural (pre-existing) and an acquired immunity for these thyreotoxalbumins which normally never enter the circulation. (7) The immunities to entero-toxins and to thyreoalbumins are entirely distinct and exhibit no interrelationship. (8) The results of animal experimentation make it probable that a greater number of diseases than is supposed depend on intestinal phenomena and insufficiency of the thyroid gland. (9) Therapeutic measures may also be deduced from these observations.

Contributions to the Physiology of Nutrition in Infants.—Bendix, in studying the effect of menstruation and pregnancy on the character of the milk-supply of nursing women, and its influence on the nutrition of the infant, concludes as follows: The mere fact of the inauguration of menstruation is not an indication for weaning the child, even when a direct effect upon the milk appears to be produced, such as an increase or diminution in quantity, apparent thinning, color changes, or slight intestinal disorders of the child during the days of the flow. Such deviations from the normal speedily readjust themselves and do the infant no permanent harm. If the child ceases to gain in weight, and there is evidence of involution in the breast, which sometimes takes place in the days following the first period, weaning or a wetnurse is to be advised. In cases in which a second pregnancy begins during lactation the author advises careful consideration of the strength of the mother and nursling and the amount of milk formed, and believes that it is justifiable to wait for some evidence of inadequate feeding or overstrain on the mother before weaning the infant.

Comparative Observations on the Value of the Mechanical and Alcohol Disinfection of the Hands as Opposed to that with Mercury Salts, Especially with Mercury Ethylendiamin (Conclusion).—Krönig and Blumberg draw these conclusions: (1) The purely mechanical methods of disinfection with water, soft soap, and brush, or with Schleich's soap give only very unsatisfactory results. (2) Ahlfeld's method of treating the hands for five minutes with water and soap, and five minutes with ninety-six-per-cent. alcohol, is also inadequate. (3) These methods are surpassed in point of efficacy by a combination of mechanical disinfection with water, soft soap, and brush, and subsequent treatment with a solution of some mercury salt. (4) In place of the usually employed 1:1,000 sublimate solution it is preferable to use an aqueous 3:1,000 solution of mercury ethylendiamin citrate. This does not irritate the cutaneous surface, does not precipitate albumin or blood, and has great penetrating power.

The Laryngoscope, July and August, 1900.

The Spoke-Shave in the Removal of Septal Spurs.—J. G. Wishart says that he has largely given up the use of the nasal saw in the removal of those projections springing from the nasal septum which present (*a*) the appearance of horns, such as occur usually far back in the nasal cavity, are bony in character, and impinge against a small area of the mucous covering of the inferior or middle turbinated surfaces; or (*b*) the appearance of shelves, usually more anterior in situation, partly cartilaginous and partly bony in character, and in length anywhere from one-quarter to one inch, and lying parallel, or almost parallel, to the floor of the inferior meatus. He applies to the site of operation pledgets of aseptic cotton moistened with a solution containing cocaine four per cent., extract of suprarenal capsule ten per cent., and trinkresol twelve per cent. When all is ready for operation, the surgeon places the left hand upon the patient's forehead and with the right draws the loop of the instrument rapidly and firmly forward, thus removing the obstruction. He claims for this procedure the following advantages: (1) the absence of bleeding till the operation is accomplished, with the advantage of non-obstruction to the vision; (2) great saving of time in operating; (3) the almost entire absence of pain or fear to the patient; (4) the satisfactory course pursued in healing.

Fibroma Involving the Tympanic Cavity.—A case of fibroma at this unusual site is reported by E. W. Fleming as occurring in a man aged forty years. One month before coming under observation the man noticed an increasing sensation of fulness in the left ear, later a discharge of pus and a solid fleshy mass nearly filling the ear. In order to effect its removal the auricle was detached and a wire loop slipped over the growth. Granulation tissue necessitated (in the course of three weeks) a thorough curettage. The patient then had an attack of rheumatism. Six months after the aural operation the following note was made of the ear condition: With the exception of a small sinus, through which issues stringy muco-pus, the external auditory canal is closed. The obstructing tissue appears to be fairly organized granulation tissue having none of the characteristics of the original growth. There are small pouting granulations at the orifice of the sinus. The patient is now gaining strength rapidly, and says he has at no time experienced any ear pain or other head symptoms. The special points of interest in the case are, first, the nature of the tumor; second, its extreme vascularity and rapid growth after partial removal, pointing alike to possible malignancy; and, third, its unusual location.

Strong Carbolic Acid Used by Mistake as a Throat Spray.—D. H. Galloway treated a man with severe tonsillitis and pharyngitis, and desired to use peroxide of hydrogen. The patient's wife brought the bottle, which was labelled as above, and about one ounce of the contents was poured into an atomizer and sprayed into the throat. The patient coughed and choked, and the doctor, getting a view of the mucous membrane of the mouth, saw that it was white and smelled the odor of carbolic acid. Examination of the bottle showed that the original label of the acid had been partly covered over by that of the peroxide. The atomizer was immediately rinsed out with hot water and filled with equal quantities of alcohol and water, which was sprayed into the patient's throat and mouth and repeated ten or a dozen times in the next fifteen or twenty minutes. During most of this time the patient was choking and strangling, almost suffocated and quite cyanotic. When he was able to breathe with some freedom a mucilage of slippery-elm bark was freely sipped. The patient recovered in about a week. The accident was caused primarily by the druggist pasting the carbolic-acid label over the original label, a thing which druggists seldom do and which should never be done.

The Physiology of Voice Production.—In an article on this subject, W. Scheppegrell says that the speaking voice should be placed as low as the voice will permit, so that it can be used without undue strain of the muscles of the vocal cords and accessory muscles, at the same time not being so low as to prevent changes in the inflections of the voice in giving expression to speech. Very frequently it is placed several tones above this, so that the constant strain from speaking places the subject in the same position as one who has ametropic vision and who feels the constant strain unless assistance is given by glasses. Fortunately, in this case, the correction is a more natural one, and the error being recognized and the subject placed under the care of one who understands the correct principles of elocution and the proper placing of the voice, the fault may be entirely corrected. Many cases of the so-called "clergyman's sore throat," chronic laryngitis, and other irritations of the throat are due to this, and unless the cause is removed recurrences will naturally be frequent until eventually the voice may be permanently injured.

Auricular Cataphoresis.—Determined to give this mode of therapy a trial, G. Ferreri made the following experiments. He used a silver-chloride battery of ten elements developing a current of five milliamperes, and in circuit with a commutator. Evidence of absorption was estimated by the effect on the pupil. As myotics eserine and pilocarpine were used, and for mydriatics hyoscyamine, scopolamine, atropine, duboisine, homatropine, ephedrine, and cocaine were used. The results of his experiments were extremely disappointing, for notwithstanding various arrangements of his apparatus, he was unable to demonstrate any absorption of the substances used. He believes that auricular therapy cannot count galvanic cataphoresis among its efficacious resources.

The Journal of Tropical Medicine, July, 1900.

Camp Fevers as seen at Massowah by Italian Observers.—Filippo Rho says that in Massowah, a region absolutely free from malaria, there is an extraordinary number of cases of fevers breaking out in extensive epidemics, especially in the less dry and less torrid season. They declared themselves suddenly, mostly without shiverings, the symptoms being pains in forehead, loins, and eyes, a foul but never dry nor cracked tongue, loss of appetite, and constipation; dry or perspiring skin, according to the temperature, which hovered between 38 and 40 C. A measly rash sometimes appeared about the neck, chest, back, and extensor surface of the limbs. Rarely diarrhœa occurred. There was a slow convalescence, with exhaustion disproportionate to the brevity of the malady. The author gives his reasons for considering these fevers as belonging to the diseases of a typhoid order. In hot climates, typhoid fever usually runs a less dangerous course than with us. He believes that many fevers of tropical and temperate climes, which are being attributed to various causes and called climatic, must be ascribed to typhoid infection.

Circumscribed Cutaneous Œdema in Brazil.—W. G. Tottenham Posnett describes six cases noted by him while he was serving as ship's surgeon to Brazil. It was characterized by swellings which appeared on the dorsum of feet and hands, shins, back and front of thighs, buttocks, back of the shoulder, and dorsal aspect of the forearms—never on the face. The swellings were never round, but oval; in the limbs the long axis of the swelling was always in the long axis of the part; those on the buttocks and shoulders had a direction downward and outward, seldom inward. The onset was sudden, accompanied by slight malaise; the swellings appearing in the morning, persisting from a few hours to several days, and causing a tingling or burning sensation. This appears to be a comparatively common affection among the English in Brazil, but rarely attacks Portuguese or Brazilians. The etiology is not known. Treatment consisted in a mixture of potassium bicarbonate, magnesium carbonate, and magnesium sulphate, which was useful in one case. Sodium sulphate seemed to be more useful in another case.

Anchylostomiasis in the Leeward Islands.—William M. McDonald says that in his report to the government he drew attention to this disease for the following reasons: (1) That up to that time anchylostomiasis was not recognized and not treated in Antigua; (2) its great prevalence throughout Antigua; (3) the severity of its symptoms in all the cases reported by him; (4) its response to treatment if attended to early. He thinks the cases that harbor the parasites, and that do not show symptoms, just as important as those suffering from anchylostomiasis, for a large proportion of those that show marked symptoms are "past praying for," and go down hill, whatever the treatment. On the other hand, those that harbor the parasite without any definite symptoms, with vigorous treatment are prevented from becoming chronic invalids, a nuisance to themselves and their relations, a burden to the State, a serious loss to their employer, and a source of great danger to their neighbors.

Leucoderma in Indian Natives.—Frederick Pearse describes a case, illustrated by a photograph, of a disease common among Indian natives. It is characterized by irregular loss of pigment forming piebald areas of skin on all parts of the body. The disease is popularly called white leprosy, but has no relation to the true kind. It occurs in children and in old people as well. Some of the natives lose nearly all their color, others lose it in patches only. The author does not know whether the lost pigment is ever recovered.

Experience an Essential of Satisfactory Radiography.—A. W. Goodspeed says that to make a radiogram of a normal hand, for example, in such a way as to show a shadow of the bones on a photographic plate, is such an easy matter that any intelligent person can accomplish the result with a very little experience, provided the apparatus is set up, adjusted, and in good working order. The event is far different, however, if, for instance, an obscure case of hip disease is brought to be radiographed, and when a correct diagnosis and proper treatment are dependent not only upon a good, clear, and undistorted picture, but upon a logical and intelligent interpretation of the same. As an almost indispensable aid to correct diagnosis Goodspeed believes that a very complete set of standard normal pictures of the various parts of the anatomy, taken under conventional and well-defined conditions, should be a part of every equipment. Careful comparison of pathological pictures with first-class standards, if the former were well executed, should not lead an experienced operator into serious error.

The Relation of Artificial Feeding to the Gastro-Intestinal Diseases of Infants.—D. H. Bergey discusses the various phases of this question, summarizing his views as follows:

The continued high death rate from gastro intestinal diseases among infants under one year of age should cause us to put forth our best efforts to combat this scourge. All known preventive measures should be employed, such as sanitary inspection and control of the production and sale of milk intended for infant feeding; the pasteurization of all milk used for infant feeding by heating to 75 C. for ten minutes, and then rapidly cooling it and preserving it in the ice chest until used; the rigid exclusion of all adulterants of whatever nature; gratuitous supply of pasteurized milk, and ice, to the poor of our large cities; the careful instruction of the laity in the process of rational infant feeding, especially of the great danger of feeding infants under eighteen months to two years of age on anything but properly prepared milk without the consent and direction of the family physician; the inculcation of the idea that the gastro-intestinal diseases of infants are frequently communicable to other infants brought in contact with such cases.

Osteoarthritis of the Spine and Hip Joints: Rhizomelic Spondylosis.—Two cases of this diseases are described by C. H. Frazier. The name was suggested by Marie, and refers to a condition in which the osteoarthritis involves the spine and joints adjacent to the trunk to the exclusion of other articulations, particularly those of the hands and feet. Several illustrations are given of the characteristic attitudes assumed by the patients, and the matter of differential diagnosis is thoroughly discussed. No cause has yet been discovered for this peculiar localization of the lesion. No specific internal treatment has yet been found.

A Study of the Physiological Action of Phenacetin.—H. C. Wood, Jr., presents the following conclusions: (1) The moderate dose of phenacetin is without any distinct action on any vital organ. (2) Large doses lessen reflexes by a direct action on the spinal cord. (3) Doses of 0.5 gm. per kilo of body weight (equivalent to a little less than one ounce for a man weighing one hundred and fifty pounds) kill by arrest of respiration. (4) Doses even up to 0.5 gm. per kilo had no distinct effect on the circulation.

Coxa Vara; Ankylosis of the Hip.—By De Forest Willard.

Medicine, August, 1900.

Ankle Sprains.—Edward H. Ochsner recommends a method of treatment which consists in careful and systematic strapping with rubber adhesive straps. These are cut from half to three-quarters of an inch in width, and the proper length, the width depending upon the size of the limb. The foot is held at slightly less than a right angle and a trifle everted. One end of a long strap is applied to the inner surface of the foot near its posterior end, brought under the heel, and up on the outer posterior surface of the leg to within a few inches of the knee. At the lower end this falls into the depression just posterior to the external malleolus. A shorter strap is now applied by placing one end to the inner surface of the heel near the sole of the foot, then bringing it around over the tendo Achillis to the outer surface of the foot, making it cover the first strap at a right angle, and passing along parallel to the under border of the sole of the foot, then over the dorsum of the little toe. Another long one is now applied, anterior to the first, overlapping it about one-third of its width; then a short one, and so on alternately until the outer anterior aspect of the ankle is reached. A hard-rolled bandage is placed over all, and the patient directed to lie still with the foot elevated until the warmth of the body has caused the plaster to adhere firmly. As a rule, the patient can walk with reasonable comfort after a few hours.

The Examination of Sputum for Tubercle Bacilli.—Carl Weidner emphasizes the necessity for a positive, infallible method of making a differential diagnosis between the tubercle bacilli and other bacilli that may be similar to them in appearance or in staining-reaction. He describes in detail the method of staining taught and practised by Guenther. Several preparations, instead of one only, ought always to be made. The absence of tubercle or tubercle bacilli may not be positive proof of the absence of tuberculosis. The repeated absence, however, of bacilli in purulent sputum nearly all authorities consider to be positive proof of the absence of tuberculosis. The number of bacilli is of no value in giving a clew to the progress or prognosis of a case. The author lays stress upon the point that we should always use a controlling stain whenever we are in doubt. We ought to have several preparations and use two methods in order to make the procedure safe.

The Treatment of Abortion.—Henry B. Stehman outlines the principles underlying this treatment as follows: (1) The rendering of the vulva, vagina, and uterus aseptic and, so far as possible, maintaining them so; (2) arresting of hemorrhage, either by use of the tampon in the cervix or vagina, or by directly emptying the uterus; (3) in inevitable abortion, the ovum, or any part of the product of conception, should be removed as early as possible; (4) intelligent curettage is invariably indicated whenever a vestige of placental decidua remains, or any suspicion of infection is in evidence, and a bacteriological differentiation is necessary both from the standpoint of prognosis and treatment; (5) when circumscribed local infection is a complication, evacuate the pus as early as possible and by the shortest route.

Annals of Surgery, August, 1900.

Note on the Relation of the Os Magnum to Tuberculosis of the Wrist Joint.—In three cases of the disease D. E. Mundell noted from skiagraphs that the disease had started in the os magnum or at least had made greatest progress in this bone. Tubercle bacilli manifest themselves in bone by a process of rarefaction; hence that bone most rarefied would in all probability be the one in which the process is most active. Ollier has emphasized the importance of juxta-epiphyseal strain in the production of tuberculosis of long bones; and, on the same principle, repeated strains on any bone may favor tuberculosis on account of minute foci of inflammation resulting from the "jarring" of the trabeculæ. Such conditions obtain, Mundell believes, in the case of the os magnum, and he describes at length the mechanical conditions which come into play with reference to this bone both in health and in injuries. It is the main bone in the wrist and is the first to ossify; it is so situated as to receive the effects of injuries from three metacarpal bones; it performs more movement in flexion and extension than the other bones; in these movements greater strain is thrown on it than on the other carpal bones, from the numerous ligaments connected with it and resisting such movements; the cancellated structure of the os magnum is uneven; that portion, the inner, which has the wider spaces, and is therefore less strong, has a richer blood supply. For the above reasons, vibrations the result of traumatisms would affect the os magnum more often than the other carpal bones, and especially that portion of it referred to above which consists of less numerous trabeculæ. The pain has been described by patients as of a burning, aching character, and is the result, in the early stage of the disease at least, of pressure on the synovial membrane between the os magnum and trapezium, because these two are more closely bound together than any of the other bones; hence the enlargement of the os magnum from the tuberculous process—though this enlargement would be very slight, for tuberculosis of bone is accompanied by very little increase in size—will be sufficient to "nip" the synovial membrane between it and the trapezium.

Malignant Disease of the Stomach and Pylorus.—W. J. Mayo takes the position that cancer at this site is a surgical disease. Surgery offers the only hope of cure, and a suspicion of gastric cancer should cause the physician to send the patient to the surgeon for exploratory incision to complete the examination. The main difficulty is in the direction of early diagnosis. The curability of cancer of the stomach depends upon: (1) the histological structure of the neoplasm; (2) its location; (3) its extension to neighboring structures; (4) lymphatic infection; (5) the general condition of the patient. It is essential that the relative value of the manifestation of the malignant process be studied, for upon a correct appreciation of the conditions present depends the whole question of treatment. The author then elaborates the foregoing propositions and describes the various operations which have been devised for the removal of the malignant growth at this site, going into considerable detail as to the technique of the operations, proper preparation of the patient, etc. He concludes by saying that the exploratory incision for suspected cancer of the stomach, instead of being a last resource, should be one of the first, and be promptly undertaken if the condition cannot be proved to be non-malignant. Complete removal of the stomach has won a foothold, but to what extent the future only can determine. The more radical believe that even if the disease has affected only a limited and apparently excisable portion of the stomach, the whole organ should be removed; that pylorectomy and partial gastrectomy are not based on correct principles, and the large percentage of local recurrences after partial operations certainly give color to this view.

Archives Générales de Médecine, May and July, 1900.

Hemorrhages of the Suprarenal Capsules.—François Arnaud gives the symptomatology of this condition, as observed in eighty cases: (1) In forty-six out of seventy-nine cases there were no appreciable signs. (2) In five cases there was a voluminous hematoma or abdominal tumor that could be perceived by palpation. The diagnosis was made in one case only during life. (3) There were peritoneal symptoms in six cases, all accompanied by tearing of the capsule with hemorrhage. (4) There were symptoms of capsular insufficiency in eight cases. (5) In fifteen cases there was sudden death, or death after three days at the most, sometimes accompanied by delirium, convulsions, contractures, coma, hypothermia, and syncope. In more than half of the cases, therefore, the hemorrhages remain latent and apparently without effect upon the organism.

Diffuse Muscular Atrophy following Slight Traumatism of the Extremities.—Gilbert Ballet and Henri Bernard thus sum up their conclusions: (1) Following a superficial cutaneous lesion, or exceptionally an articular lesion, there may be a complex of symptoms characterized by a special form of muscular atrophy. (2) This amyotrophia affects all the muscles of the limb to the same extent; it is an atrophy *en masse*, or diffuse atrophy. It is slight, the circumference of any part of the limb rarely being diminished more than 2 or 3 cm. It is not accompanied by any reaction of degeneration. (3) These symptoms cannot be due to a true ascending neuritis, nor to a degeneration of the axis. They must be related to a slight diffuse lesion, or to some slight nutritional disorder of the medullary cells of the anterior cornua.

Malarial Household in Meaux; Rôle Played by House Plants.—M. Vicente describes three cases of malaria (proved to be such by an examination of the blood, and by the reaction to quinine) in the mother and two children of a family living in a house so situated as to be apparently free from malarial infection, and in winter. There were three oleander bushes in the house, a plant which in Algeria is supposed to give malaria. This bush harbors an insect which plays the part so frequently played by mosquitos in transporting the malarial germ from the swamps to man. There were innumerable colonies of this "flea" on the plants above-mentioned, and on the furniture and floor, and the clothes and hair even of persons in the house.

The Pancreas in Cirrhosis.—E. Lefas having examined the pancreas at the autopsy of a number of persons who died of cirrhosis, gives the following results of his observations: In atrophic cirrhosis, the pancreas is enlarged, with some sclerosis of the splenic extremity, and cells in fatty degeneration. In hypertrophic biliary cirrhosis, there is no increase in volume, but increase in interlobular connective tissue. In cardiac cirrhosis, there are no special changes in the pancreas, but occasional changes in the blood-vessels. In hypertrophic pigmentary cirrhosis, the author has not found special alterations in the pancreas, dut Hanot and Chauffard found considerable peri-lobular sclerosis.

Acute Fecal Intoxication.—M. Deschamps says that it has been demonstrated that the sudden admixture of fecal matters with water used for drinking may, in addition to special accidents, produce troubles that can be divided into two distinct clinical types. The first are characterized by toxic gastro-enteritis, the phenomena being those of intoxication rather than of infection, and resembling those which follow the ingestion of putrefied food. The second are choleriform in nature, or in some severe cases choleraic.

Hysterical Laryngeal Hypokinesis.—C. Chauveau describes a case in which hysteria was caused by grippe and affected the air passages, the larynx, and finally the nerve centres presiding over the motor functions of the larynx, giving hypokinesis, with hemiplegic motor and sensory troubles of the same side of the body and of the velum palati.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HEAT WAVE—CENTENARY OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND—WAR HOSPITALS COMMISSION—PROFESSOR OSLER AT THE POST-GRADUATE COLLEGE—THE INGLEBY LECTURES.

London, July 27, 1900.

The London season—as interpreted by the votaries of fashion—closes to-day, and next week we shall hear that Mayfair is empty, although many of its most useful inhabitants will remain. The season goes out with a marked change of weather. The heat-wave which has been so oppressive for the last three weeks appears likely to pass by. A fall of 10 or 12 in the thermometer yesterday portended a change, and this afternoon we had a thunderstorm with copious rain. Next week we shall have an exodus of many doctors as well as of society people.

The ceremony of conferring honorary fellowships in celebration of the centenary of the Royal College of Surgeons of England was the occasion of a gathering far more brilliant to the eye than such functions usually are with us.

The costumes of the numerous ladies present and the British and foreign doctors' gowns lit up the theatre of the London University gayly. Few people recognized Mr. Treves in the dashing-looking officer in a hussar uniform who occupied one of the seats on the platform. Not the least imposing figure was that of the Prime Minister in the gold-barred robes of Chancellor of the University of Oxford. Lord Rosebery, too, was conspicuous in his Cambridge doctor's robes. Both these statesmen received honorary fellowships, as did some thirty distinguished European, American, and colonial surgeons, including von Bergmann, Lannelongue, Albert, Ollier, Keen, Warren, and others.

Professor Keen, who was received with great applause, made a speech distinguished by its excellence of matter and manner. Referring to the improvements in surgery, he said Warren and Lister had made them possible by their discoveries of anæsthesia and antisepsis.

The ceremony took place in the theatre of Burlington House, lately the abode (if such a disembodied spirit can have been said to have an abode) of the late London University. Always a picturesque figure, the president, Sir William MacCormac, showed to advantage in his brilliant surroundings and conferred the fellowships with impressive dignity. His reception was the more cordial because the company appreciated his services in South Africa—services which were gracefully referred to by Professor Keen.

Before the actual celebration a deputation from the Council waited on the Prince of Wales to present the diploma of the honorary fellowship to His Royal Highness. The Prince, having accepted the diploma, signed his name and so began the roll of this new honorary fellowship. The diploma says, "We, the Royal College of Surgeons of England, do hereby admit," etc. This does not express the fact that the college consists of thousands of members who have no vote in appointing the twenty-four gentlemen who constitute the Council, and who thus arrogate to themselves the name of the college. It should read, "We, the Council," etc.

There was a conversazione at the college on Wednesday evening, when the guests were received by the president and vice-presidents. On Wednesday and Thursday demonstrations were given illustrating the work of the laboratory, and each morning Professor Stewart, conservator, conducted visitors round the museum and gave a demonstration of some of the chief objects of interest.

The address of welcome by the president was an effective one, and it is said will be published together with biographical notices of the sixty-one masters and presidents who have held office during the last hundred years. The address itself goes further back, for the president attempted a sketch of the progress of the art of surgery from about the close of the second century.

The commission on the war hospitals held its first sitting on Tuesday, when some evidence was taken as to the state of preparation prior to the outbreak of war. It would seem that there was in store very inadequate provision, and that, of course, the necessary provision could not be obtained without time, but further evidence will be forthcoming. The commission will shortly sail for the Cape, and on its return will perhaps take more evidence in this country. Mr. Burdett-Coutts has made himself still more ridiculous by insinuating in Parliament that the commissioners will not be impartial. Then he declared that civil surgeons at the front were bound down not to disclose hospital secrets or scandals. Mr. Wyndham, Under-Secretary for War, being questioned as to this by Dr. Farquhar-

son, was able to deny it. Mr. Coutts further urged that the truth could not be obtained without special protection being afforded to all who gave evidence. Mr. Balfour declared that the precautions taken by the commission which would be made royal, were ample, and the suggestion made conveyed an uncalled-for insult on officers and others.

You know that we have recently established a post-graduate college here. The promoters have secured some excellent lecturers, and the institution seems likely to be of service. At the opening of the museum lately Prof. William Osler delivered an address in which he ably advocated a resort to study at intervals in order to avoid becoming fossilized, and told us how widely polyclinics and post-graduate courses were appreciated in America. He gave, too, some particulars of his own work in this department, and said it was superfluous to dwell upon the great advantages London offers for study by graduates and practitioners, considering that here are collected more sick people than in any city in the world. The unequalled facilities afforded by our special hospitals and their elaborate equipments he thought quite counterbalanced the absence of concentration of material so convenient in Vienna. The organization necessary is no longer lacking since the establishment of this college. The value of the museum as a means of practical instruction was first illustrated by John Hunter, and the college is indebted to a man with a truly Hunterian mind—Mr. Jonathan Hutchinson, to whom Dr. Osler paid a high tribute, in the course of which he said that when anything turns up on which text-books are silent and cyclopædias dumb he advised his students to look up the "Archives of Surgery," as, if not there mentioned, it must be something very much out of the common. He then drew an amusing picture of the routinist and the rationalist practitioner. No one, he said, needs more renovation than teachers; upon none does intellectual staleness steal more relentlessly, and the profession has suffered sorely from intellectual old-fogyism. Then he went on to say that men above the age of forty are rarely pioneers, rarely creators in science or literature. Over that age men are in danger of premature senility.

Professor Osler is thought so much of on this side that it may seem heterodox to interpose a *caveat*, and yet much work has been done for the world by older men. I might claim some of them as scientific, but science is essentially modern and its work appropriate for the younger men—though they will carry it on to the next generation. In older branches of intellectual work surely older men have accomplished much. Take literature, which Dr. Osler mentioned—one example will suffice: Milton was old and blind when he produced "Paradise Lost."

The Ingleby lectures at Birmingham were this year delivered by Dr. O. J. Kauffmann, who devoted them to the neuroses of children, confining his attention to the more common forms. Among the practical observations which marked the lectures was a distinction between migraine and recurrent paroxysmal headaches. The sensory symptoms of migraine, the unilateral commencement of pain, and the sickness and vomiting are the prominent marks, but other headaches may alternate with migraine. Moreover, the vasomotor symptoms and the fluctuations in the blood-pressure so pronounced in typical migraine are seldom, if ever, quite absent from recurrent headaches of a simple kind, and both are produced by exactly the same causes. In these, and, indeed, in most of the neuroses, constipation and other digestive disorders are pretty constant, and Dr. Kauffmann laid stress on the toxæmic condition that might thus arise. Overfeeding or faulty feeding was accordingly blamed. Excessive amount of meat is quite liable to set up a state of epileptic tension. Undigested food is not merely irritant; it is often the source of a toxæmia, particularly when constipation exists and has probably begun such a process. The first remedy, then, is proper diet. Beyond this medicines to get the bowels into a regular and healthy action must be employed. These are aperients, alteratives, and antiseptics. These are far superior to tonics, which are of only slight utility, and when there is any degree of auto-intoxication are injurious.

LETTER FROM NEW ZEALAND.

(From Our Special Correspondent.)

A CASE OF SUSPECTED PLAGUE—DESPOTIC POWERS OF THE PREMIER—THE PLAGUE IN AUSTRALIA.

AUCKLAND, N. Z., July 9, 1900.

ON Sunday, June 10th, a man who had been at work all the previous week was taken ill with febrile symptoms and vomiting, headache, etc. As he was a member of a club, his wife sent for the club doctor. He continued ill all the week until Thursday, the doctor stating that it was a bad case of "blood poisoning." No restrictions were placed on visitors, no disinfectants were employed in the house. On Thursday a trained nurse was obtained, who took the patient's temperature at 5 P.M. It was then 101 F., pulse 120, respiration 32. That evening he read the newspaper in bed. Next morning, temperature 100.5 F., pulse 100, respiration 36. Ordered whiskey 3 i. every two hours. The temperature rose on Friday afternoon to 104.4 F., pulse 120: respiration to 44, 52, 56, and about 7 30 P.M. he died. In the afternoon a second medical man was called in. The patient had been in bad health for months, with blotches and pimples on his face. He drank quietly and unknown to his wife a good deal of beer. He had been cleaning out a drain on the Saturday before he was attacked, and had a small sore on a toe of the left foot. There was an enlargement of the femoral glands on the left side with red streaks of inflamed lymphatics. The two doctors declared it to be a case of bubonic plague, and gave a certificate accordingly. The people in the house were all quarantined, and three houses besides, in which were persons who had been in contact with the sick man. The patient died on Friday, June 24th, and on Saturday, July 7th, the inmates of the house were released from quarantine, no case of sickness of any kind having occurred among them. Altogether twenty-five "contacts" were quarantined; six others (doctors and undertakers) who had been in contact with the corpse were allowed at large, and among the thirty-one there was not a single case, even suspicious, after a fortnight's quarantine! Obviously the conclusion is that this was either not a case of bubonic plague, or that plague is not, in our climate and to our population, an infectious disease. I believe the case to have been one of simple septicæmia, probably by the introduction of septic matter through the sore on the toe.

The case has created great excitement in New Zealand and great indignation here, as exceptional legislation was passed in order to meet the emergency. We have a premier here, with a large majority, and he rules us with a rod of iron. By the new act anybody can be shut up, any property, including houses, can be taken and destroyed, without compensation, and all such acts are declared to be outside the jurisdiction of the courts of law. The plague is dying out in Sydney, but spreading to other Australian towns. The death rate in Sydney is below the average in spite of plague.

A WORD THROUGH THE FAMILY PHYSICIAN TO THE MOTHERS OF DEAF CHILDREN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I am moved to write you under the above title by the frequent instances that come to my notice in which a timely word from the family physician to the mother of a deaf child would have made him a genuine benefactor.

Every physician some time during his practice meets with a case of total deafness or imperfect hearing in a child. In nine cases out of ten the deafness, whether partial or total, was not noticed by him on first seeing the child, and was not accepted as a fact by the parents for a long time after the doctor's suspicions were aroused and expressed. I have known many cases in which the child was four years old, and more, before the parents were convinced that it was so deaf as to need special attention. The result is that much valuable time is lost which, if properly used, would have had a most beneficial effect upon the future welfare of the child.

It is not generally realized by either physicians or parents how great a handicap even slight deafness is to a child in hindering the acquisition of language and such general information as comes from the ordinary conversation of those around him. If the truth was known, many so-called stupid children are only hard of hearing and have been so from infancy.

If the child's hearing is imperfect, the fact should be known as early as possible, and steps taken to determine the nature of the difficulty, and what means should be employed to develop the hearing, when possible, or to train the other senses if there is little hope of improvement in the hearing.

The first step, of course, is to determine whether the suspicion of deafness is correct, and if so, to what extent the hearing is impaired: and this is not so simple a thing as it might seem. In fact, there are not many more puzzling things than to determine satisfactorily these facts in the case of a child at the age of two years. Slowness in learning to talk may be an indication, but many children of normal hearing are slow in beginning to speak. Direct tests, such as calling when the child's back is turned, or clapping the hands, are apt to be misleading, for often a child with perfect hearing will pay no attention to such things if his mind happens to be occupied with something else, and I have frequently seen deaf children turn on such an occasion,

either as a coincidence or from perceiving vibration, to which they are often surprisingly sensitive. Deafness also presents so many peculiarities in relation to pitch as to add difficulty to the task. I have had instances in which sounds of a certain pitch were entirely unheard, while for other notes the hearing was almost acute. I have known instances of inability to hear certain vowels, while others were heard with considerable distinctness.

There are also certain mental defects that simulate deafness very closely, but, of course, require very different treatment. These and many other possibilities have to be known and taken into account in pronouncing upon the deafness of a child and in determining what course is best to pursue.

In general it may be said that if a child is slow in beginning to express itself in words, passes its second birthday, we will say, without having surely uttered any words except "papa" and "mamma," which words are generally spoken even by deaf children simply in imitation of the movements of the mother's lips, then it is time to prove that deafness is or is not the cause.

In the case of even a totally deaf child, the laugh and cry are perfectly natural, a thing which often deceives both mother and physician. If the child is wholly or partially deaf, but in every other respect physical and mental is normal, there have probably been many little occurrences before its second birthday to cause the mother to wonder if there may not be something wrong. But this suspicion is seldom strong enough to lead to a consultation with a specialist, though the matter may be mentioned to the family physician, and he should either carefully test the child himself or have the parents consult some one for the purpose.

It is no very unusual thing for an aurist to declare that a child is totally deaf who has really only some form of tonal deafness, and possesses enough perception of sound to be of great service if it was properly educated and developed. But the dictum of the specialist is accepted as final and the latent hearing-power is allowed to lie dormant until it is too late to do much in the way of awakening and educating it. But even if an aurist is not always of service in determining the state of the child's hearing, he should certainly be consulted at once in regard to the state of the child's ears, as soon as the fact of deafness is suspected.

Every mother, of course, wishes the child to speak and understand the speech of others, and to be as intelligent as other children. It is for the purpose of bringing this about, so far as it is possible in the case of a deaf child, that an early knowledge of the deafness is desirable. Few mothers realize, even after they are certain that their child is deaf, that the first thing they should do, if they wish him to become as proficient as possible in speech and the understanding of speech, is to consult some competent authority on the subject of the oral education of the deaf, and put themselves under the guidance of such a person in their dealings with the child. In this way they can often save years of time in the later stages of the child's education, and at the same time attain results which would be impossible if the beginning had not been made so promptly. A word to this effect from the family physician would have great weight and would be the means of conferring an incalculable benefit upon both parent and child.

JOHN D. WRIGHT.

42 West 76th Street.

AN EARLY EXPERIENCE WITH THE RAIN BATH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have no desire to enter the lists in the controversy of a mooted question, viz., that of priority in having brought to public notice in this country the advantages of the rain bath. However, recently I recalled that a number of years ago, when post-bellum literature referring to the Civil War was still popular, I had read something which, despite facetious narration, bears upon the subject.

Junius Henri Browne, war correspondent and author of "Four Years in Secessia," relates in the last-named volume his experience in Missouri while with Fremont's army. In one place he speaks with fervor of some evils of camp-life, animate and other. One hot night, having shed his garments for good cause, he resolves upon a certain line of action, which is described as follows: "A few minutes after, a storm which had been gathering burst with fierce lightning, heavy thunder, and torrents of rain. A happy idea seized me. I caught up my saddle and bridle and placed them on my sable steed, Festus, which stood neighing to the tempest, a few feet from camp. I mounted the fleet-footed horse and, nude as Apollo Belvidere, cried 'go!' to the restive animal, and off we sped, to the amazement of the sentinels, through the darkness and storm. Every few minutes the lightning blazed around us with a lurid sheen, as we went like the wind through the tempestuous night. Festus enjoyed it, as did his rider, and six swift-speeding miles were passed ere I drew the rein upon the neck of the panting beast covered with white flecks of foam. I paused and felt the fleas had been left behind. The pelting rain and rushing blast had been too much for them; while the exercise had made my attireless body glow into a pleasant warmth. Festus galloped back, and soon I was in the tent, rolled so closely in a blanket that no new attack could reach me. . . . So ended that memorable *noche triste*, an exemplification of the Scriptural declaration, 'The wicked flee when no man pursueth.'"

It will be noted in the above that both the stimulating and the cleansing effects of the rain were realized, therefore in a sense priority in employment of this method of hydrotherapeutics was established with a vengeance. And who will not say that thirty-nine years ago a layman's inspiration conceived and at once brought into practical effect all the benefits of a natural spray bath?

BERNARD OETTINGER.

DENVER, COLO., Aug. 2, 1900.

THE SPECTACLE AND EYEGLASS HABIT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your issue of August 4th contains an abstract from an article by N. B. Jenkins, which appeared in the *New York Medical Journal* of July 28th, entitled "The Spectacle and Eyeglass Habit." The following expressions the writer deems strange, if not absurd, in view of the facts and truths that are to-day incontrovertibly established: "The wearing of spectacles or eyeglasses out-of-doors is always a disfigurement, often an injury, seldom a necessity. The old rule, 'Wear glasses all the time,' should be changed to 'Wear glasses just as little as possible.'"

As concerns the disfigurement, it suffices to say that much of this can be obviated by the proper regard for cosmetic effects. There is no doubt that a face can be made to look ludicrous or comely, the effect produced depending chiefly on the oculist's knowledge of symmetry, harmony, and the angular or pleasing relation of lines and forms. But the statement that glasses are "seldom a necessity" is inexcusable. It is incorrect and could be excused only on the grounds that the author wrote from the standpoint of a layman, or one who deals with old and settled facts as if he were discoursing on the nebular hypothesis or other questions of undoubted controversial category. It is not necessary to state that an anomalous or ametropic eye, which cannot be restored by operative or other means to a normal state, needs a support as much as a short leg needs a high heel, etc., and what is more potent and true is, that it needs it as long as that abnormality exists; in-doors or "out-of-doors," or wherever vision is desired. It cannot be doubted that an eye having the proper correction will feel strained when the correcting lens is removed, as would the short leg when the heel is removed from the boot; but this Dr. Jenkins declares, with an unheard-of sweeping statement, to be "because they have wrong glasses." "The right glasses," he states, "can be put on and taken off at any time with ease, and no more discomfort will follow than when putting on or taking off a hat."

As far as the physical exertion of taking off and putting on is concerned, this is true, but in no other sense. In fact, it is possible only when eyes are *not* properly corrected. Even an incorrectly fitted glass you can take off and get much relief. It is an accepted fact that when you correct an astigmatism of 1 D, you relieve the strain that the patient makes in trying to obtain clear vision. Take this lens of 1 D cylinder and put it on a normal eye, and that eye will encounter the trouble that the patient with 1 D of astigmatism, without a lens, encounters, habit excepted. To say that a lens correcting an error of refraction, a heterophoria, or any anomaly is only temporarily necessary, is reversing not only pure logic, but turns topsy-turvy the laws upon which hygiene, sanitation, and healing are based.

The individual with healthy normal eyes can as consistently and with as much comfort put on 3 D+ lenses when he goes into the street as the 3 D hyperope can remove his when he goes out-of-doors, barring what of custom, disregard, and disuse habit may have established. The individual with 4 or 5 of exophoria can gain but little by suffering in "bits" when his comfort is complete and continual by wearing prisms constantly.

The individual with a marked congenital refractive trouble of one eye having caused an amblyopia, should be told to wear his glasses all the time, and educate and develop his defective vision.

T. T. BLAISE, M.D.

MASON CITY, IOWA.

Therapeutic Hints.

Cystitis.—

℞ Liquor potassæ ..... ʒ ij.
Mucil. acaciæ ..... ʒ i.
Tinct. hyoscyami ..... ad ʒ iv.
M. S. Teaspoonful every four hours.

—Burnside Foster.

Pruritus Ani.—

℞ Sodii hyposulphit ..... 30 parts.
Acid. carbol. ..... 5 "
Glycerini ..... 50 "
Aquæ ..... 450 "
Apply frequently by means of wet compresses.

—*Practitioner.*

Summer Diarrhœa in Children.—Salol is to be employed when symptoms indicate an implication of the upper bowel; naphthalin, however, is to be used when the colon appears to be chiefly involved. None of the bismuth preparations is superior to the subnitrate.

℞ Bismuthi subnit ..... ʒ iss.
Bismuthi salicylatis ..... gr. xv.
Tinct. rhei aromat ..... ʒ ss.
Aquæ destill. ..... ad ʒ ij.
M. S. Teaspoonful every three hours.

—Hayward and Butler.

Amyl Nitrite inhalations cautiously made quiet severe after-pains.—Winterburn.

Rachitis and Chronic Malnutrition.—

℞ Yolk of egg ..... No. ij.
Glycerini ..... ʒ ss.
Ol. oliv ..... ʒ iij.
Add one minim of creosote to each two drachms.
M. ft. emuls. S. Teaspoonful after food three times a day.

—*Practitioner.*

Mouth Wash and gargle for sweetening the breath:

℞ Acid. salicylici,
Sodii bicarb.,
Sacchari ..... āā gr. xv.
Spt. vini rect. ..... ʒ i.
Spt. menth. pip. ..... gtt. x.
M. S. Teaspoonful in a small cupful of hot water.

—Palmer.

Gonorrhœal Arthritis.—

℞ Syr. ferri iodidi ..... ʒ ss.
S. At dose gradually increased.

—Wilson.

Chorea.—

℞ Ol. gaultheriæ ..... ʒ ij.
S. Apply ʒ ss. to ʒ ii. to the skin with friction until systemic effects are noted.

—Luigi.

Hemorrhoids.—

℞ Chrysarobin ..... gr. xij.
Iodoformi ..... gr. v.
Ext. bellad ..... gr. viij.
Petrolati ..... ʒ i.
M. S. Apply.

—*Journ. de Méd.*

Senile Bronchitis.—

℞ Ammon. carb ..... gr. v.–x.
In three ounces of milk several times daily.

—Ex.

Tuberculous Laryngitis in the later stages may be best treated by insufflation, the patient himself using a bent glass tube for the purpose.

℞ Iodoform. 8
Cocainæ hydrochlor 0.08
Morphin. hydrochlor. 0.04

The pain is greatly relieved and the voice may be restored.—Leduc.

Tuberculous Joints.—A sun-bath of several hours' duration each day should be given. A firm bandage over wool dressing should be used during intervals.—Millioz.

The Mask of Pregnancy.—For uterine chloasma apply:

℞ Zinci oxidi 0.20
Hydrarg. ammoniat. 0.10
Ol. theobrom.,
Ol. ricini ..... āā 10.
Essen. rosæ ..... gtt. x.
M. ft. ung.

Erysipelas.—Apply mercurial ointment either in its full strength or diluted with other ointments according to the nature of the case.—Dematteis.

Measles with unconsciousness, delirium, carpologia, involuntary evacuations, etc., was markedly improved by an injection of 10 c.c. of antistreptococcus serum.—Edgar Gillrie.

Myocarditis.—Caffeine in small dose varying from day to day may be kept up for years with benefit in a great variety of chronic heart affections. It is especially indicated in weakness due to disturbance of pulmonary circulation.—Lemoine.

Eclampsia.—In coma introduce a stomach tube and inject a solution of chloral (gr. xlv. to lx.) directly into the stomach. If given by the rectum it is often expelled. When the mouth cannot be opened, pass through the nasal fossæ.—Fochier.

Chorea.—The good effect of belladonna is most marked in recent cases. Arsenic may be combined with it in rheumatic cases. Thirty minims or more of the tincture may be given to a child in a hospital ward, every four hours for ten days or more.—Overend.

Morphine is depended upon at the Willard Parker Hospital to maintain the heart's strength in diphtheria. Small doses hypodermatically (gr. $\frac{1}{15}$–$\frac{1}{10}$) are given. Strychnine, alcohol, and nitroglycerin are also employed.

Reflex Cough in Children.—Treat the cause. Hacking night-coughs are mostly due to nasopharyngeal obstruction. Paroxysmal hacking cough in emaciated children with normal temperature is held by Warner of London to be due to unbalanced central nerve action.—*Pediatrics.*

Enteric Fever with Excessive Diarrhœa.—Give compound tincture of benzoin, beginning with ♏ v. in water every two hours, and double the dose if the diarrhœa does not markedly decrease within twelve hours. Besides the antiseptic there is supposed to be an antipyretic action.—J. C. Potter.

To Bring on Labor.—The use of the Krause sound or the Farnier balloon are means largely employed. They prepare for rather than provoke labor. The Farnier divulsor at times gives good results when the part presses upon the neck. Manual dilatation is the method of choice, for it permits of complete and rapid dilatation and should be adopted in all cases in which it becomes necessary to terminate labor quickly.—Léon Weill.

Nitrogen Gas by Intra-Pleural Injection.—(1) It will have a permanent place in the treatment of pulmonary tuberculosis. (2) Bad results or unpleasant effects following the injections have not been personally observed. (3) No patient under my care has been cured by the method, although a great many have been distinctly benefited, with a marked recession of all the active symptoms. (4) The local improvement is not so marked as the constitutional. (5) A decided gain in the bodily weight was noted in every case subjected to this treatment. (6) It has never failed promptly to stop hemorrhages from the lungs, even in severe cases.—H. P. Loomis.

Society Reports.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-eighth Annual Meeting, Held at Ipswich, July 31, and August 1, 2, and 3, 1900.

GENERAL SESSIONS.

(Special Report for the MEDICAL RECORD.)

First Day—Tuesday, July 31st.

At eleven o'clock the members of the association assembled in the church of St. Mary-le-Tower to take part in the usual opening service. The church was well filled with the members and their families, and the mayor and aldermen of Ipswich, who were present in state, attended by the bearers of sword and mace. The sermon was preached by the Right Rev. John Sheepshanks, Lord Bishop of Norwich, who took for his text Ecclesiasticus xxxvii. 13, 14, 15, and 16:

"Honor the physician with the honor due unto him, for the use ye may have of him, for the Lord hath created him.

"For of the Most High cometh healing, and he shall receive honor of the king.

"The skill of the physician shall lift up his head, and in the sight of great men he shall be in admiration.

"The Lord hath created medicines out of the earth, and he that is wise shall not abhor them."

At three o'clock the opening general session was held in the Higher-Grade School hall, the members in attendance (less than two hundred) being called to order by the retiring president, Dr. John Ward Cousins.

Resolutions of Sympathy.—He began by proposing a resolution of sympathy by the association with the Queen and all the members of the royal family in the death of the Duke of Edinburgh, the reigning prince of Saxe-Coburg Gotha, whose demise from cancer had recently occurred. This resolution having been unanimously adopted, the president delivered a short address upon retiring from the chair. He said that the membership in the association was steadily increasing, there being now 18,382 members of the parent association and of its various branches in the colonies. There were still, however, too many non-members among the medical men of the United Kingdom, and he would urge upon them the duty and the advantage of enrolling themselves in this great representative body. He spoke of the work of the medical men in South Africa, and expressed confidence that, when all the testimony concerning the alleged hospital mismanagement was in, it would be found that no blame attached to the army medical corps. There ought, he said, to be specialists in the medical department of the army. There should be surgeons to treat the wounded, physicians to treat the sick, and sanitarians to prevent sickness. After referring to the all too premature death of his predecessor in office, Sir Thomas Grainger Stewart, he introduced his successor, Dr. William Alfred Elliston, the president-elect for 1900–1901.

After the applause which greeted him had subsided, Dr. Elliston said that his first pleasant duty as president of the association was the nomination for honorary membership of H.R.H. the Prince of Wales, K.G., Hon. F.R.C.P., Hon. F.R.C.S. The nomination was seconded by Dr. Thomas G. Roddick, of Montreal, who said Canadians were very much attached to the Prince of Wales and would all be glad to learn that it was now permitted to him to practise medicine and surgery throughout the British dominions. The honor the association was about to bestow upon him was shared by a Canadian, Lord Strathcona and Mount Royal, and the speaker hoped both honorary members would attend some future meeting of the association in Canada. The election was unanimous.

A vote of thanks to the retiring president was then passed.

Report of the Council.—A motion calling for the adoption of the report of the Council and of the treasurer's statement was the signal for the usual dispute over matters of little general and no scientific interest. In the course of the wrangle Mr. Victor Horsley called attention to an article in *The British Medical Journal* which had displeased him, and accused the editor of dishonesty, and to emphasize his disapproval he moved that the following paragraph be omitted from the report of the Council: "The Council has every reason to believe that the journal has proved increasingly useful to members. The publication of the proceedings of the last annual meeting and of its sections was commenced immediately after the conclusion of the meeting, and was completed before the end of November."

DR. DAWSON WILLIAMS, editor of *The Journal*, in a straightforward speech disproved Mr. Horsley's charges, and maintained that he had written the objectionable leader in good faith, with no thought either of *suppressio veri* or of *suggestio falsi*. The offended member of the Council then agreed to withdraw his motion of censure on condition that his remarks and those of the editor be printed *verbatim* in *The Journal*.

The general session was then adjourned to reconvene at 8:30 in the Lyceum Theatre. After another resolution of sympathy with the Queen and royal family in their loss had been passed, the mayor of Ipswich welcomed the members of the association to the town, and spoke of the pleasure the citizens of Ipswich had experienced in the selection of their fellow-townsman, Dr. Elliston, as president of this representative body of British medical men.

The President's Address.—DR. WILLIAM ALFRED ELLISTON then delivered an address entitled, "Some Incidents in the Evolution of the Modern Physician." During the Dark Ages, he said, men of learning had spent their time in translating and repeating what the Greeks had taught, until at last they had come to believe that Ptolemy, Galen, and Aristotle had settled most of the scientific questions, and that no one had any right to doubt their decisions. The one exception to this apathy to science on the part of Englishmen was Roger Bacon. Thomas Linacre introduced what was termed the "new learning" from Italian universities, and Sir Thomas More, in his "Utopia," showed the effect upon health of pure water, the structure and ventilation of the house, the garden at the back, the width of the street, cleanliness, isolation of the infected sick, care of children, abattoirs, etc. The great event of the sixteenth century, so far as medicine was concerned, was the success of Thomas Linacre in persuading the king to grant a charter to a small body of medical graduates, who were thenceforth called the Royal College of Physicians. It gave them the sole power to license to practise physic in London or within seven miles' radius, with other privileges which were confirmed by a statute of Henry VIII., and extended to the whole of England. Soon after the birth of the new learning, the work of Vesalius, aided by his contemporaries Fallopius and Eustachius, raised anatomy to a science based upon the dissection of the human body itself, in addition to that of animals, but this scientific advance did not exercise its influence at once, as might be seen from the records of highly esteemed practitioners of the day. In the sixteenth century there were already established physicians, surgeons, and apothecaries, the first being men of education, the others with a few exceptions belonging to the less-educated classes until the rise of the nineteenth century. At the beginning of the seven-

teenth century the original researches of Gilbert and Harvey completely altered the position of Great Britain in scientific advance, and from that time to this Englishmen have taken a conspicuous part in the solution of the many scientific problems and discoveries of the last three centuries. Gilbert established the magnetic nature of the earth, and conjectured that terrestrial magnetism and electricity were two allied emanations of a single force. He described the properties of the magnet. Harvey's name was immortalized in the annals of medicine for his discovery of the circulation of the blood, the results of his observations were the more remarkable when the scanty instruments and appliances then available were considered. In 1645 a small body of students assembled at Oxford, who in 1662 were to be known as the Royal Society, which was the oldest scientific society in Great Britain and one of the oldest in Europe. Soon after its incorporation the society published papers by Malpighi, who by the microscope revealed the minute infinite particles of living bodies. A little earlier Boyle and John Mayow anticipated some of the great discoveries in chemistry and physiology a century later. Practical medicine was developing in this century; a pharmacopœia had been issued, cinchona bark was introduced, botanical gardens were established. In surgery the growth was slow, but Nathaniel Highmore discovered the cavity in the superior maxillary bone, and Thomas Wharton the duct of the maxillary gland. In the early part of the eighteenth century Boerhaave, of Leyden, shared with Dr. Hales, the great English chemist, the honor of founding the science of organic chemistry. At this time there was no systematic medical training in the British isles; but there were isolated attempts at special instruction. The study of anatomy increased, but there was a great amount of popular prejudice against dissection. William Hunter was the first great teacher of anatomy in London, and was selected and advanced by Dr. James Douglas, who discovered Douglas' pouch. The most remarkable scientific advance was in the science of chemistry. Black, Priestly, Cavendish, and Rutherford discovered respectively carbonic acid, oxygen, hydrogen, and nitrogen. In practical medicine Dr. Richard Mead communicated to the Royal Society Borrow's discovery of the acarus scabiei. Dr. James Lind published a treatise on scurvy, suggesting the use of fruit and vegetables and lemon juice. He also discovered that the steam of salt water was fresh. Toward the end of the century Sir Edward Jenner completed his observations upon the prophylactic power of cowpox against the virulence of smallpox. Dr. Baillie published his "Morbid Anatomy," which was the first book on the subject in English. He described ulcers of the stomach and of typhoid, the changes of the liver in cirrhosis, abdominal cysts, and other pathological conditions. The scanty means of education possible in London and the absence of medical societies in the eighteenth century were remarkable. Surgeons and apothecaries were supposed to be able to pick up a sufficient smattering of their work by attending a hospital for a few months, and physicians were educated elsewhere. The education of Edinburgh was far ahead of London; medical societies and periodicals flourished there before coming south. In London, in 1783, there were five lecturers on anatomy, three lecturers on surgery, and three lecturers on the practice of medicine. The eighteenth century closed with an immense advance all round in general science, particularly in chemistry and electricity. Of the physicians and surgeons in active practice early in the nineteenth century there were many of great distinction—Lettsom, Matthew Baillie, Edward Jenner, James Gregory the younger, Edward Grigby, Cline, Abernethy, Sir Astley Cooper, Sir Charles Bell. The long roll of eminent surgeons of later days began with several distinguished pupils of John Hunter. Abernethy and Cooper had great fame as lecturers and bold and philosophic surgeons. To Charles Bell were owed anatomical and physiological discoveries of the highest importance in connection with the nervous system. The important legislation of the nineteenth century was the Apothecaries Act of 1815. Previous to this act the education of the medical practitioners of England and Wales was entirely optional on their part. About 1850 a preliminary examination in arts was instituted as a necessary and independent requirement before proceeding to the medical curriculum. In 1858 the Medical Act became law. Women were admitted to practise in 1876. In 1878 the pharmaceutical chemists were licensed by act. In 1832 the Anatomy Act afforded facility for the practical study of anatomy, and did away with "body-snatching." The growth of the medical press began with the efforts of William Sharman, M.D., who in 1810 edited a journal called *The New Medical Physical Journal, or Annals of Medicine, Natural History, and Chemistry*. In 1815 Thomas Wakley founded *The Lancet*, with the primary object of disseminating much-needed information hitherto regarded as the exclusive property of members of the London hospitals, and also with the view of exposing the family intrigues that influenced the appointments in the London hospitals and the medical corporations. It was fiercely opposed for ten years. The brilliant work done by physicians and surgeons in this century would take too long to enumerate; but the speaker alluded to Bright's discoveries in the pathology of kidney disease, Hodgkin's observations on the lymphatic glands and the spleen, and Addison's publications in regard to the relationship between anæmia and disease of the suprarenal capsules. Sir William Gull, Graves, Gerhard, Hughes Bennett, and many other great names swelled the list. In surgery, more than in medicine, the tendency had been to specialize. Dentistry, ophthalmology, and aural surgery were branches of the science. The most brilliant advances had been in abdominal surgery, and operations that forty years ago were deemed unjustifiable were now performed with success in every hospital, thanks to Sir Spencer Wells, Keith, Clay, Greig Smith, and Lister. William Jeaffreson, of Framlingham, was the first surgeon in England to perform the modern operation of ovariotomy by a small central incision. The treatment of mental affections had greatly improved in this century, great thanks being due to William Tuke, Sir John Bucknill, and others. The two great discoveries of the nineteenth century in connection with medicine and surgery were the antiseptic treatment (due to Lord Lister) and the use of anæsthetics. Robert Liston was the first surgeon in the country to use ether, which was discovered by Faraday. Parkes was the founder and first teacher of military hygiene, and was a great factor in, if not the founder of, the science of modern hygiene. The special departments which concerned the surroundings of man had been the subjects of legislation during the present century. State medicine as an organized department of administration was of modern growth. The first act in this direction was the Towns Improvement Act of 1847, and in 1848 a general Public Health Act, embracing the whole of England except the metropolis, was passed. The Local Government Board was created in 1871, and in 1875 the existing laws were digested into the Public Health Act of 1875. In conclusion the president alluded to the fact that medical education was the most costly of all the modern professions, which was due to the long period of time required for the medical curriculum, and to the multiplication of qualifications, which he regarded as

a fashionable absurdity. There was necessity for the highest mental training, but the elements of science should be more generally taught in school life.

At the conclusion of the address a vote of thanks was proposed by Mr. Howard Marsh, seconded by Dr. I. H. Cameron, of Toronto, and carried unanimously.

Greeting to Colonial and Foreign Representatives.—Dr. John Ward Cousins then spoke a few words of welcome to the foreign and colonial guests, to which Drs. Nicolaysen, of Christiania, and Roddick, of Montreal, responded.

Second Day—Wednesday, August 1st.

The second general session was held in the hall of the High Grade School.

The Meeting of 1901.—After a list of names of the new and retiring members of the council had been read, the president of the council, Dr. Roberts Thomson, announced that, upon invitation of the Gloucester branch, the council suggested that the next meeting of the association would be held in Cheltenham under the presidency of Dr. George Bagot Ferguson. This recommendation was adopted by a vote of the association, with thanks to the members of the Gloucester branch for their courteous invitation.
